- The radial artery is protected within the proximal field of dissection.
- The TMC joint capsule is identified in the depths between the APL and EPB tendons. At this point, it is useful to insert a Freer elevator at the presumed TMC joint space (**TECH FIG 1D**) and use fluoroscopy to verify correct position (**TECH FIG 1E**).

TECH FIG 1 • A. Incision is marked between midpoint of thumb metacarpal and radial styloid. **B.** The branches of the radial sensory and lateral antebrachial cutaneous nerves are identified and protected. **C.** The abductor pollicis longus and extensor pollicis brevis tendons are identified, and the interval between them is planned for exposure. **D.** A Freer elevator is used to identify the location of the TMC joint before making a

capsular incision. **E.** Fluoroscopy confirms the correct location of the joint. **F.** The capsule of the TMC joint is incised, and capsular tissue is circumferentially elevated from the thumb metacarpal and trapezium.

- A longitudinal incision is made full thickness through the capsule to elevate the capsule from the metacarpal and the trapezium. An attempt should be made to preserve the edges of the capsule neatly for later closure (**TECH FIG 1F**).
- Elevation of the capsule circumferentially from the metacarpal may cause detachment of the APL tendon insertion and it does not need to be reattached.

Fitting the Metacarpal Base to the Trapezium

- The thumb metacarpal base is delivered into the wound using two small Hohmann retractors.
- Using a rongeur or a slow-running bur, the metacarpal base is denuded of cartilage and subchondral bone, and the proximal medullary bone is fashioned into a ball or cone shape (**TECH FIG 2A,B**).

A

B

C

D

E

TECH FIG 2 • A. The metacarpal base is delivered into the wound, and a rongeur is used to fashion the medullary bone into a cone shape. **B.** Healthy cancellous bone is visualized. **C.** In preparing the trapezium surface, an option to allow for adequate bony contact is to use a K-wire to drill multiple holes into the trapezium at a 45-degree angle directed toward the center of the bone. **D.** A small osteotome is then used to excavate the central bone to allow the cone-shaped metacarpal base to fit into the trapezium. **E.** The metacarpal is fit onto the prepared surface of the trapezium.

- The articular surface of the trapezium is then removed and the medullary bone of the trapezium is fashioned into a cup shape to accommodate the cone of the metacarpal base. This can be done with a low-speed power bur or by using an awl.
- Another option is to use a K-wire to drill multiple holes angled at 45 degrees toward the center of the trapezium (**TECH FIG 2C**). The holes are drilled sequentially at 2- to 3-mm intervals to create a circle, and the circumscribed cone-shaped fragment is then excavated with a small straight osteotome (**TECH FIG 2D**).⁶
- Attention to detail is important when shaping the surface of the trapezium, as it may be a thin and degenerated bone with relatively little volume to allow for error. It is essential to be certain that the center of the “cone” has been denuded of cartilage or cortical bone and contains exposed medullary bone.
- The metacarpal is fit onto the prepared surface of the trapezium (**TECH FIG 2E**).

Positioning the Thumb and Fixation

- At this point, attention is turned to proper positioning of the thumb. Ideal position is approximately 45 degrees from the coronal and sagittal planes of the hand. Slight pronation of the thumb tip may assist with pinch to the more ulnar digits.

- Proper position is confirmed by seeing that the pulp of the thumb rests on the radial aspect of the index middle phalanx with the fingers in a relaxed, closed fist (**TECH FIG 3A**).
- Positioning should be secured using a K-wire for provisional fixation. This can initially be driven antegrade through the base of the thumb metacarpal toward the MCP joint and then reversed and driven retrograde to secure the base of the metacarpal to the trapezium.
- Once position is visually adequate, bony apposition is checked with fluoroscopy. Any areas of inadequate bony contact should be supplemented with cancellous bone autograft.
- Provisional K-wire fixation is maintained while placing a plate. Our preference is to use a locking 2.3-mm T-plate with the wings of the T placed over the trapezium and the long aspect of the plate extending onto the metacarpal shaft (**TECH FIG 3B**).
- Fluoroscopy should be used liberally to ensure that screws do not penetrate nearby joints (eg, STT) or the FPL tendon sheath. Once fixation is achieved, the K-wire is removed (**TECH FIG 3C,D**).

TECH FIG 3 • A. The thumb is positioned with it resting on the radial aspect of the index middle phalanx with fingers in gentle flexion. A K-wire is used to secure the position prior to plate fixation. **B–D.** A locking T-plate is used to maintain the position of the thumb, and multiple fluoroscopic images are obtained to evaluate the plate position, the contact of the bony surfaces, and the length of the screws to avoid unwanted penetration into the STT joint or flexor pollicis longus.

- The capsule of the TMC joint should ideally be closed with buried suture.
- Supplement general anesthesia with local anesthetic injection before skin closure.
- The skin is closed with horizontal mattress sutures. Take care to avoid

branches of the RSN during closure.

- The hand is dressed with short-arm thumb spica splint, leaving the IP joint free.

■ Dorsoradial Approach to Thumb TMC Joint Arthrodesis With K-Wire Fixation

- This procedure is identical to the above technique except that in place of a plate and screws, three 0.045-in. K-wires are used for fixation.
- This technique is most appropriate for patients with soft bone that will not accommodate a locking plate, such as patients with rheumatoid arthritis. We do not recommend use of K-wire fixation for fusion in patients with osteoarthritis.
- The first wire should follow the planned axis of bone fusion and may be driven using the antegrade (via the exposed TMC joint) followed by retrograde technique.
- The remaining two wires should be driven retrograde through the metacarpal into the trapezium at a divergence of 10 to 20 degrees from the axis of the first wire.
- Wires should not penetrate the STT joint.
- Pins are capped and left outside the skin for office removal at 6 to 8 weeks.
- Closure and dressings are as above.

PEARLS AND PITFALLS

Simulate fusion preoperatively

- Place the patient in a hand-based thumb spica splint for several weeks preoperatively to ensure the patient understands what postoperative motion and hand function will be like.

Preparation of the bone

- Careful preparation of the bone surfaces is essential for positioning and improved bony contact. This involves complete removal of articular cartilage and subchondral bone while maintaining the cup and cone formation of the joint.

Bone graft

- Be prepared to harvest bone graft if needed to ensure excellent

	bony contact between fused surfaces. Our preference is to augment the fusion site with distal radius bone graft.
Nerve branches	■ Take great care to avoid damage to branches of the radial sensory nerve to prevent postoperative pain syndromes.
Position	■ Discuss positioning of the thumb preoperatively with the patient. Ideal position can be estimated by placing the thumb pulp over the index middle phalanx with the fingers resting in a flexed position.

POSTOPERATIVE CARE

- The short-arm thumb spica splint placed in the operating room is maintained for 2 weeks.
- Sutures are removed at 2 weeks, and the patient is placed into a short-arm thumb spica cast.
- If plate fixation is used, the cast is removed at 4 to 6 weeks postoperatively.
- If Kirschner wire fixation is used, the cast and pins are removed at 8 weeks.
- After cast removal, patients are given a custom-fabricated, removable forearm-based thumb spica splint leaving the interphalangeal joint free until definitive signs of bony healing are seen on x-ray.
 - Typically, bony healing on x-ray appears between 12 and 14 weeks (**FIG 1A–C**).
 - A CT scan can be performed to confirm union at 8 to 10 weeks (**FIG 1D**).
- Range of motion is initiated after cast removal with the help of a certified hand therapist (**FIG 1E,F**).

OUTCOMES

- Functional outcomes are typically excellent following thumb TMC joint arthrodesis. Clinically, it may be difficult to tell the difference between the thumb operated upon and the normal thumb.⁶
- Patients and surgeons should expect the operation to relieve the pain of arthritis, improve grip, and restore good stability to the thumb ray.⁴
- With proper positioning of the TMC joint in arthrodesis, compensatory motion of the MCP and STT joints typically allows patients to adduct the thumb to touch the base of the proximal phalanx of the index finger and to oppose the thumb to the tips of all fingers.⁵
- Thumb retropulsion and abduction from the plane of the palm will be decreased when compared with the unoperated side but are adequate to allow

grasp around relatively large objects such as jar lids. Pinch strength is typically equal to the contralateral side.⁷

FIG 1 • Radiographs (**A–C**) and CT image (**D**) confirm healed arthrodesis at 10 weeks. **E,F**. Postoperative photos of patient with left thumb CMC locking plate arthrodesis.

COMPLICATIONS

- Nonunion is the most concerning complication and occurs at a reported rate of

13%.⁸ Nonunion can be minimized by ensuring excellent apposition of cancellous bony surfaces, using bone graft and careful fixation technique. Careful attention to shaping of the cup and cone surfaces and avoiding the use of high-speed, heat-generating power saws may also help to prevent nonunion. Rigid stabilization with plate and screws may shorten casting time, but definitive increased overall union rate over K-wire fixation has not been shown.⁵ Nonetheless, it is our preference to use locking plate fixation over K-wire fixation.

- Hardware-related pain or hardware prominence is a potential complication when using plate and screw fixation that may require return to the operating room.
- Hardware malposition (eg, within the STT joint) is a potential complication that is best avoided by intraoperative use of fluoroscopy in multiple planes.
- Radial nerve neuritis and complex regional pain syndrome are potential complications of this operation that are best avoided by careful identification and protection of nerve branches intraoperatively. However, the surgery should be approached with the knowledge that these complications may occur even despite careful surgical technique.
- Patients may complain of an inability to place the palm flat on a table or with difficulty in placing the hand in a pocket. These concerns are best addressed with thorough preoperative education and splinting.

Section IV: Wrist Fractures and Carpal Instability

14 Arthroscopic Examination of the Wrist

CHAPTER

Emily Krauss and Amy M. Moore

DEFINITION

- Wrist arthroscopy is a diagnostic and therapeutic tool to evaluate radiocarpal, intercarpal, and carpal pathology. Wrist arthroscopy has been described using both wet (fluid infiltrate) and dry techniques. Treatment applications include arthroscopic surgical procedures and arthroscopic-assisted open procedures.

ANATOMY

- Standard wrist arthroscopy portals are dorsal due to the relative lack of neurovascular structures (**FIG 1**).
- Portals to assess the radiocarpal joint are named relative to their location between extensor tendons. Volar portals, if used to assess the radiocarpal joint, are placed to avoid the major neurovascular bundles. The midcarpal joint can be assessed either by the dorsal midcarpal portals or by the volar radial midcarpal portal. The volar portals are used in select situations to evaluate the dorsal ligaments and are not standard portals for most situations.
- Standard diagnostic arthroscopy ports are described in Table 1.¹
- Portals with special indications are listed in Table 2.¹

FIG 1 • Dorsal wrist arthroscopy portals.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Wrist arthroscopy is a diagnostic adjuvant to patient history and clinical examination.
- Patient evaluation is not complete without a thorough history of onset, aggravating and alleviating factors, history of trauma, occupational and repetitive motion history, and a complete history of interventions including injections, imaging, and surgical procedures.
- Physical examination should include an evaluation of wrist tenderness, tendinous pathology, carpal instability, distal radioulnar joint (DRUJ) pathology, and reproduction of symptoms with wrist loading. Details of a complete wrist physical examination are essential but beyond the scope of this chapter.

IMAGING

- Plain radiographs including posteroanterior, lateral, oblique, and clenched-fist views of the wrist may contribute to the differential diagnosis.
- A wrist arthrogram to test for triangular fibrocartilage complex (TFCC) tear can be unreliable in ulnar-sided wrist pain (sensitivity of 76%).²
- Wrist arthroscopy continues to be of value as a diagnostic tool in these cases. Arthroscopy is also useful in patients unable to obtain a 3T MRI or in patients suspicious for injury that could benefit from arthroscopic-assisted surgical intervention.

NONOPERATIVE MANAGEMENT

- Wrist arthroscopy is indicated as a diagnostic technique in patients with persistent wrist pain with no response to an appropriate trial of conservative management, including activity modification, splinting, nonsteroidal anti-inflammatories (NSAIDs), and cortisone injection.
- It may also be used as a diagnostic technique to stage the degree of injury (extent of ligament tear and articular wear) or pathology for further surgical planning.

SURGICAL MANAGEMENT

- Diagnostic indications:
 - Cartilage injuries
 - Chondromalacia
 - TFCC injury staging
 - Ligamentous instability (scapholunate interosseous ligament [SLIL] injury, lunotriquetral interosseous ligament [LTIL] injury)

Table 1 Standard Dorsal Wrist Arthroscopy Portals

Portal Name	Anatomic Landmarks	Purpose
1-2	Radial to EPL tendon at dorsum of snuff box	Inflow. Allows access to the radial styloid, scaphoid, lunate, and articular surface of the distal radius
3-4	Distal to Lister tubercle, between EPL and EDC tendons	Used as the main radiocarpal arthroscopic viewing portal

4-5	Distal to DRUJ. Follow ring finger metacarpal proximally, between EDC and EDM	Used as the main instrumentation portal for the radiocarpal joint; allows visualization of TFCC
6R	Radial (R) to ECU tendon	Instrumentation portal, visualize the TFCC and the ulnar wrist ligaments (ulnolunate, ulnotriquetral, and lunotriquetral)
6U	Ulnar (U) to ECU tendon	Outflow; allows access to dorsal rim of the TFCC or for instrumentation when debriding the volar LTIL
Radial midcarpal	In line with second metacarpal proximal to the capitate; identified by a depression between the capitate and scaphoid	Allows visualization of the scapholunate and lunotriquetral articulations, the STT joint, and the distal pole of the scaphoid
Ulnar midcarpal	In line with the 4th metacarpal, 1 cm distal to the 4-5 portal; identified by a depression at the lunotriquetral-capitate-hamate joint	Allows further visualization of the lunotriquetral articulation, distal lunate, and triquetral hamate articulation; used for instrumentation of the articulations

ECU, extensor carpi ulnaris; EDC, extensor digitorum communis; EDM, extensor digitorum minimi; EPL, extensor pollicis longus; DRUJ, distal radial ulnar joint; STT, scaphotrapeziotrapezoid joint; TFCC, triangular fibrocartilage complex.

- Wrist arthritis evaluation (intactness of lunate facet and midcarpal joint in

salvage procedure surgical decision-making)

- Kienbock disease diagnostic staging (using 3-4 portal only to preserve vascular pedicle for a 4-5 extensor compartment artery vascularized bone graft)

■ Treatment indications:

- Ganglion excision
- TFCC tear debridement or repair of foveal tears
- Resection of radial styloid (radial styloidectomy in impingement)
- Ulnar styloid excision
- Proximal hamate excision (proximal arthritis in type II lunate)
- Chondroplasty
- Arthroscopic-assisted fracture reduction
 - Distal radius fractures (comminuted or depressed articular fragments, evaluation of associated scapholunate ligament injuries)
 - Scaphoid fractures (using 4-5 portal for waist and proximal pole fractures)

Table 2 Special Indication Portals

Portal Name	Anatomic Landmarks	Purpose
Scaphotrapeziotrapezoid radial (STT-R)	In line with the index metacarpal just radial to the EPL at the level of the STT joint	Allows visualization and debridement of STT joint
Scaphotrapeziotrapezoid ulnar (STT-U)	In line with the index metacarpal just ulnar to the EPL at the level of the STT joint	Allows visualization and debridement of STT joint
Triquetrohamate	Ulnar to the ECU tendon at the level of the TH joint	Inflow/outflow. Allows visualization and debridement of the TH joint
Volar radial	Radial to the FCR tendon at the proximal wrist flexion crease, essentially through the floor of the FCR tendon sheath	Visualization of the DRCL and the volar aspect of the SLIL, visualization during DRUJ fracture reduction
Volar ulnar	Interval between flexor	Visualization of the

	tendons and flexor carpi ulnaris and the ulnar neurovascular bundle	dorsal radioulnar ligament and volar aspect of the lunotriquetral ligament. Aids in repair or debridement of dorsal TFCC tears
Volar DRUJ port	Accessed through same skin incision of the volar ulnar portal, but the capsular entry is 5 mm to 1 cm proximal to the ulnocarpal capsular entry point	Volar aspect of DRUJ

ECU, extensor carpi ulnaris; EPL, extensor pollicis longus; DRCL, dorsal radial carpal ligament; DRUJ, distal radial ulnar joint; FCR, flexor carpi radialis; SLIL, scapholunate intercarpal ligament; STT, scaphotrapeziotrapezoid joint; TFCC, triangular fibrocartilage complex; TH, triquetrohamate.

- Septic wrist (complete irrigation through radiocarpal and midcarpal portals)
- Dorsal wrist capsular release
- Volar wrist capsular release (standard dorsal portals such as 3-4 and 6R; protect radioscapophcapitate ligament to prevent ulnar translation of carpus, and volar neurovascular structures and tendons can be at risk during release)
- Contraindications:
 - Marked wrist swelling
 - Distortion of surface landmarks
 - Large capsular tears
 - Neurovascular compromise
 - Bleeding disorders
 - Infection
 - Specifically for dry wrist arthroscopy: using thermal probes, lasers, any heat-generating instrument

Preoperative Planning

- Equipment (**FIG 2A**)
 - 2.7-mm, 30-degree-angle scope with camera for the standard wrist arthroscopy and evaluation of the carpus

- 1.9-mm, 30-degree-angle scope with camera for the DRUJ
- Fiberoptic light source
- Video monitor, printer for intraoperative photos, or digital system for direct video recording
- Instrumentation:
 - 3-mm hook probe
 - Motorized shaver for debridement
 - Diathermy unit
- Ancillary equipment:
 - Motorized 2.9-mm bur for bony debridement or resection
 - Suture repair kits including TFCC repair kit or Tuohy needle for facilitating ligament repairs
- Equipment setup (**FIG 2B**)
 - Commercially available wrist arthroscopy traction tower
 - Above-elbow tourniquet
 - Shoulder holder
 - 5- to 10-lb sand bags or weights attached to arm sling for countertraction

Positioning

- The patient is positioned supine on the operating room table with the arm abducted at the shoulder and placed on an arm table.
- An above-elbow tourniquet is placed and the arm rested in a shoulder holder, with 5- to 10-lb weights attached to the arm sling (for countertraction).
- The arm is exsanguinated and the tourniquet insufflated prior to placing the fingers of the examination hand in the traction tower. Total traction force is generally 10 lb (4.5 kg).
- For use of dorsal arthroscopic examination portals, the surgeon sits at the patient's head facing the dorsum of the patient's wrist. For volar portals the surgeon sits over the patient's axilla (**FIG 3**).
- Ensure the arthroscopy camera is white-balanced and that the light source does not rest on the drape or the patient while turned on, as burns can occur.

FIG 2 • A. Arthroscopy equipment. *Top row from left to right:* 22-gauge needle with 5-cc syringe of normal saline, 15 blade scalpel, mosquito or tenotomy scissors, blunt cannula, scope introducer port, 2.7-mm 30-degree arthroscopy, 18-gauge Jelco needle, small arthroscopy shaver, shaver apparatus. *Bottom row from left to right:* 3-mm probe, straight foreign-body grasper. **B.** Intraoperative ConMed Linvatec TractionTower Extremity Traction Device setup with diagram.

FIG 3 • Patient positioning for left wrist arthroscopy. Above elbow sterile tourniquet, countertraction above-elbow straps, traction device with 10 lb of traction. Surgeon sits at patient head for dorsal approach.

Approach

Classic “Wet” Wrist Arthroscopy

- A structured approach to wrist arthroscopy is important for efficiency and good visualization.
- Portals are established by palpating surface anatomic landmarks, prior to inserting a 22-gauge needle into the joint space. If inserting into the 3-4 portal first, the needle should be inserted 10 degrees palmar to account for the volar inclination of the radius.
- The joint is then injected with 5 cc of saline and subsequent aspiration to confirm position within the wrist joint.
- Vertical or transverse (within natural wrist creases) shallow incisions are made

to avoid injury to dorsal sensory nerve branches, and a blunt mosquito or spreading tenotomy dissection is used to dissect the soft tissue down to the wrist capsule.

- The wrist capsule is then pierced (by holding the instrument like a dart) and a blunt trocar fitted with an inflow valve is inserted to introduce the scope cannula into the wrist.
- An 18-gauge angiocatheter can be placed in the 6U portal for sufficient outflow if wet technique performed.
- Structures that should be visualized in any standard arthroscopy include radius articular surface; the proximal scaphoid, lunate, and triquetrum; the SLIL both from radiocarpal and midcarpal; the LTIL both from radiocarpal and midcarpal; the radioscapophcapitate ligament; the ulnolunate (UL) ligament; the ulnotriquetral (UT) ligament; the articular disc of the TFCC; and the radial and peripheral TFCC attachments.
- Diagnostic wrist arthroscopy usually begins with the dorsal 3-4 portal to evaluate the volar ligaments. However, establishing dorsal portals first but beginning the examination using the volar radial portal to visualize the palmar SLIL and dorsal radiocarpal ligament (DRCL) can minimize iatrogenic trauma to the dorsal capsular structures and errors in diagnosis.
- A standard dorsal diagnostic arthroscopic examination uses primarily the 3-4 portal and combinations of the 4-5 portal and 6R to fully visualize the structures. From the 3-4 portal, visualization of the entire radiocarpal joint should be possible, using the 4-5 or 6R portals for probe insertion. 6U is primarily used for fluid outflow or for instrumentation for the palmar LTIL treatment.

Dry Wrist Arthroscopy

- Dry wrist arthroscopy is less commonly performed but has some theoretical advantages. However, with regard to safety with shaving or thermal procedures, we recommend the wet technique.
- Advantages:
 - Avoids fluid extravasation
 - Avoids risk of fluid-associated compartment syndrome
 - Less soft tissue swelling, capsular distention, possibly resulting in less postoperative pain
 - Larger portals and larger instruments
 - Larger portals facilitate more surgical procedures using arthroscopic

technique (eg, partial wrist fusion).³

TECHNIQUES

■ Diagnostic Arthroscopy

- Begin with the 3-4 portal distal to Lister tubercle between extensor pollicis longus (EPL) and extensor digitorum communis (EDC) tendons.
- After placement of a 22-gauge needle with a 10-degree volar tilt trajectory, inject and aspirate 5 cc of saline to confirm placement within the radiocarpal joint.
- Make a short superficial incision followed by blunt dissection using tenotomy scissors to the wrist capsule and bluntly puncture the dorsal wrist capsule. Gently insert the blunt trocar for the arthroscope (2.7-mm 30-degree angle).
- An 18-gauge angiocatheter can be inserted at the 6U portal for fluid drainage
- The 3-4 portal is a “workhorse” portal of wrist arthroscopy allowing a nearly panoramic examination of the radiocarpal joint.
- Throughout the arthroscopy, evaluation should include articular surfaces, synovitis, loose body identification and removal, and the integrity of wrist ligaments.

■ Radial Structures

- Begin radially to examine the articular surfaces of the distal radius, proximal scaphoid, and proximal lunate. The dorsal aspect of the scaphoid is also visualized. Some features of the DRC joint capsule are also seen radially.
- The radioscapophcapitate (RSC) ligament is seen originating from the tip of the radial styloid and passing distally anterior to the proximal pole of the scaphoid.
- Identify the interligamentous sulcus separating the RSC and the long radiolunate (LRL) ligaments as a landmark for orientation (**TECH FIG 1**). The LRL arises from the palmar rim of the distal radius and passes anterior to the proximal pole of the scaphoid.
- The short radiolunate ligament (SRL) is just ulnar to the LRL, seen as an

amorphous structure with surface blood vessels. The ligament passes vertically and integrates with the SL ligament in the proximal anterior third.

- The scapholunate ligament can then be seen covering the remaining proximal and distal aspects of the scapholunate joint and is fibrocartilaginous in this section. The ligament is frequently the same color and brightness as the articular surfaces and may be a concave or a convex bulge across the scapholunate joint. The SL ligament should be followed, by lowering the arthroscope parallel to the long axis of the forearm and turning the scope camera, as it courses dorsally to the reflected dorsal radiocarpal (DRC) ligament of the joint capsule. Note any signs of hemorrhage, synovitis, and attenuation (**TECH FIG 2**).
- Just ulnar to the SL ligament, the SRL ligament originates from the volar rim of the radius at the lunate fossa and forms the volar joint capsule, insetting on the proximal lunate. Ulnar and continuous with the SRL is the UL ligament. There may be a perceptible fold between the two ligaments.
- The DRC joint capsule may be visualized dorsally, generally after examination of the LT and TFCC. The DRC is normally generously lined with synovium in this region.
- Table 3 covers the 3-4 portal field of view.

TECH FIG 1 • A. Diagram of a right wrist from dorsal approach, with 3-4 portal view marked. Note the

radioscaphocapitate (*RSC*) ligament radially and the long radiolunate ligament (*LRL*) in the field of view. **B.** Radioscaphocapitate and long radiolunate ligaments as viewed intraoperatively from the 3-4 portal, scaphoid above.

TECH FIG 2 • A. Diagram of right wrist, dorsal arthroscopy, indicating arthroscopic view of the scapholunate (SL) ligament from radiocarpal joint using the 3-4 portal. **B.** Intraoperative view of synovitis of the SL ligament from the radiocarpal joint. **C.** SL ligament probed by 3-mm probe from radiocarpal joint.

Table 3 3-4 Portal Field of View

Surface Anatomic Landmark: Distal to Lister tubercle, between EPL and EDC

Portal Field of View

Portal Name	Radial	Central	Volar	Dorsal/Distal	Ulnar
3-4 Portal	Scaphoid and lunate fossa, volar rim of radius	Proximal scaphoid and lunate, dorsal and membranous SLIL	RSC, RSL, LRL, ULL	Oblique views of DRCL insertion onto dorsal SLIL	TFCC radial insertion, central disk, ulnar attachment, PRUL, DRUL, PTO,

■ Ulnar Structures

- A 4-5 portal can also be used to visualize the UL ligament and UT ligaments; however, in most patients, adequate examination can be accomplished by 3-4 portal plus a midcarpal arthroscopy.
- From the radiocarpal joint, immediately ulnar to the UL ligament is the UT ligament inserting on the volar edge of the triquetrum. The prestyloid recess can then be visualized at the junction between the UT and the palmar radioulnar (PRU) ligaments.
- Using the 4-5 portal, the pisotriquetral orifice can be visualized just anterior to the proximal articular surface of the triquetrum. Reposition the arthroscope to visualize the articular surface of the pisiform and the flexor carpi ulnaris (FCU) tendon passing through the orifice.
- Moving dorsally, the proximal region of the lunotriquetral ligament (LT) is localized by identifying the sulcus or concavity in the otherwise convex articular surfaces of the lunate and triquetrum (**TECH FIG 3**). Note any signs of hemorrhage, synovitis, or attenuation.
- Table 4 covers the 4-5 portal field of view.

TECH FIG 3 • A. Diagram of right wrist, dorsal

arthroscopy, indicating arthroscopic view of the lunotriquetral (LT) ligament from the radiocarpal joint using the 3-4 portal. **B.** Intraoperative view of the LT ligament from the radiocarpal joint.

Table 4 4-5 Portal Field of View

Surface Anatomic Landmark: Between EDC and EDM in Line with Ring Metacarpal, Slightly Proximal to the 3-4 Portal

Portal Field of View

Portal Name	Radial	Central	Volar	Dorsal/Distal	Ulnar
4-5 Portal	Lunate fossa, volar rim of radius	Proximal lunate, triquetrum, dorsal and membranous LTIL	RSL, LRL, ULL	Poorly seen	TFCC radial insertion, central disk, ulnar attachment, PRUL, DRUL, PTO, PSR

■ TFCC Evaluation

- From the 4-5 portal, the articular disc of the TFCC can be seen proximal, interposed between the dorsal radioulnar (DRU) and palmar radioulnar (PRU) ligaments. The articular disc is fibrocartilage and may be the same color and brightness at the articular surface of the lunate fossa (**TECH FIG 4A,B**).
- A 3-mm probe inserted from the 6R portal can be used to palpate the transition from the articular surface of the distal radius to the articular disc. The probe can be used to estimate the resting tension of the disc by pushing and releasing the probe pressure on the disc. Hypermobility of the articular disc is described as a trampoline sign (**TECH FIG 4C**).
- The dorsal radioulnar (DRU) and palmar radioulnar (PRU) ligaments should be identified as they converge toward their ulnar attachments.
- In patients with ulnar-sided wrist pain, it may be useful to use the volar ulnar portal to assess the palmar LTIL and dorsal radioulnar ligament and the

region of the extensor carpi ulnaris subsheath. This portal also allows for assessment of the radial TFCC attachment.

- TFCC tears can be arthroscopically classified according to Palmer's classification to guide conservative, arthroscopic, or open treatment (**TECH FIG 5**).⁴
- TFCC repair can be accomplished using instrumentation introduced through the 6U portal, although some authors advise open repair, particularly at the ulnar styloid, to avoid injury to the dorsal cutaneous branch of the ulnar nerve at the 6U portal.
- Table 5 covers 6R portal fields of view.

TECH FIG 4 • **A.** Diagram of right wrist, dorsal arthroscopy, indicating arthroscopic view of the triangular fibrocartilage complex (TFCC) using the 3-4 portal. **B.** Intraoperative view of the TFCC articular disc (*bottom*), fovea (*far center*), and lunate proximal articular surface above. **C.** Intraoperative arthroscopic view of a 3-mm probe, inserted through the 4-5 portal, testing an intact TFCC articular disc.

Portal Field of View

Portal Name	Radial	Central	Volar	Dorsal/Distal	Ulnar
6R Portal	Poorly seen	Proximal lunate, triquetrum, dorsal and membranous LTIL	ULL, ULT	Poorly seen	TFCC radial insertion, central disk, ulnar attachment, PRUL, DRUL, PTO, PSR

■ Midcarpal Arthroscopy

STT Joint

- Midcarpal examination can be performed from either the radial or ulnar midcarpal port or occasionally the scaphotrapeziotrapezoid joint (STT) port.
- When using the radial midcarpal portal, orientation can be quickly established by recognizing the concave surfaces of the proximal row articular surfaces and the dramatically convex articular surface of the head of the capitate and pole of the hamate (**TECH FIG 6**).
- Identify the cleft at the proximal extent of the capitolunate joint.
- Reorient the scope to direct it distally into the dorsal aspect of the midcarpal joint over the STT joint. This is accomplished by dropping the scope into a line tangential to the plane of the forearm.
- Rotation of the arthroscope in this region will visualize the STT joint and the curvature of the distal articular surface of the scaphoid. A cleft can be visualized between the trapezium and trapezoid and the radial aspect of the STT ligament along the lateral aspect of the STT joint.
- Moving the arthroscope proximally from the STT joint, the scaphocapitate (SC) articulation comes into view. The SC joint is a “tight” joint, and transverse fibers of the SC ligament are sometimes seen but not always due to difficulty positioning the arthroscope.

SL Joint

- As the arthroscope is continually drawn more proximally, the distal cleft of the SL joint is visualized. The SL joint should be visualized from at least two portals to change the orientation of view and prevent a false sense of a step-off.
- When visualizing the SL joint, take care to ensure that the arthroscope is not exerting pressure on either the scaphoid or lunate, forcing them out of alignment.
- The SL joint should be evaluated visually and by using a 3-mm probe according to the Geissler grading scale (**TECH FIG 7**).⁵
- Under normal conditions, it is difficult to pass an arthroscopic probe into the SL or LT joint and rotate it. When there is a SL ligament disruption, the scope can enter into the joint space; this is referred to as the “drive-through sign” (**TECH FIG 8**).
- From the midcarpal portals, the volar midcarpal joint capsule, with its generous synovial stratum, can be assessed, as well as the “space of Poirier” by palpating the volar capsule with the probe to detect a groove between the

arcuate ligament (RSC and UC) and the lunate.

Ulnar Structures

- A complete assessment of the midcarpal joint includes the ulnar structures. Moving the scope ulnarly, the distal articular surface of the lunate can be inspected as well as the LT joint cleft (**TECH FIG 9**).

TECH FIG 6 • **A.** Diagram of the right wrist, dorsal arthroscopy of the midcarpal joint from the radial midcarpal portal. **B.** Visualization of the capitolunate joint allows for orientation in the midcarpal joint.

TECH FIG 7 • **A.** Diagram of right wrist, dorsal arthroscopy of the midcarpal joint, indicating arthroscopic field of view of the SL joint from the radial midcarpal portal. **B.** Hemorrhagic synovitis at the scaphocapitate joint.

TECH FIG 8 • **A.** Diagram of the right wrist. **B.** “Drive-through sign” of the SL interval indicating a Geisler-

type IV injury.

TECH FIG 9 • **A.** Diagram of right wrist, dorsal arthroscopy of the midcarpal joint, indicating arthroscopic field of view of the LT joint from the radial midcarpal portal. **B.** Intraoperative arthroscopic view of the capitate and hamate above, and **(C)** a 3-mm probe inserted through the ulnar midcarpal portal testing an intact LT joint.

Table 6 Radial Midcarpal Portal Field of View

Surface Anatomic Landmark: Radial Side of the Third Metacarpal Axis Proximal to the Capitate in a Soft Depression Between the Capitate and Scaphoid

Portal Field of View

Portal Name	Radial	Central	Volar	Dorsal/Distal	Ulnar
Midcarpal radial portal	STT joint, distal scaphoid pole	SLIL joint, distal scaphoid, distal lunate	Radial limb of arcuate ligament, ie, continuation of RSC ligament	Proximal capitate, CHIL, oblique views of proximal hamate	LTIL joint, partial triquetrum

- The LT can be palpated with a 3-mm probe and can also be graded using the Geissler grading scale.⁵

- Further ulnar movement can assess the palmar ligaments (ulnocapitate, triquetrocapitate, and triquetrohamate) after gently scraping the volar capsule synovial stratum.
- By dorsally rotating the scope at this position, the articular surfaces of the distal triquetrum (spiral shaped) and the proximal hamate (elliptical shape) can be inspected.
- Further ulnar movement of the scope will visualize a large joint recess and the “bare area” on the capitate neck and head and the pole of the hamate; however, due to excess synovial tissue, this view is often obscured.
- Tables 6 and 7 cover the radial and ulnar midcarpal portal fields of view, respectively.

Table 7 Ulnar Midcarpal Portal Field of View

Surface Anatomic Landmark: 1 cm Distal to the 4-5 Portal, Aligned with the Fourth Metacarpal, at the Lunotriquetral-Capitate-Hamate Joint

Portal Field of View

Portal Name	Radial	Central	Volar	Dorsal/Distal	Ulnar
Midcarpal ulnar portal	Distal articular surface of scaphoid	Distal lunate	Volar limb of arcuate ligament, ie, continuation of triquetrocapitolunate	Oblique views of proximal capitate, CHIL, proximal hamate	LTIL joint, triquetrum

PEARLS AND PITFALLS

Incisions

- Superficial longitudinal (or transverse) dermal incision followed by blunt dissection with a mosquito (or tenotomy dissection) to protect the extensor tendons and dorsal sensory nerve branches

Portal placement	■ Reposition the trocar if not inserting easily, to avoid chondral injury. Always use the blunt trocar to enter into the joint.
Arthroscopy fluid	■ Normal saline is injected to confirm placement of portals in the wrist, and arthroscopic examination can be performed either with or without fluid. However, use of heat-producing equipment should only be performed with arthroscopic fluid to avoid thermal injuries. We recommend the wet technique.
Inadequate views	■ Synovitis, fractures, ligament tears, and tight wrist capsule may limit the field of view during wrist arthroscopy requiring use of more portals to adequately assess the wrist.
Traction	■ Wrist traction often diminishes throughout the examination and should be readjusted to avoid inadvertent chondral injury from instruments.
Standardization	■ A standard approach to wrist arthroscopy optimizes efficiency and ensures a thorough and complete examination of the wrist.

DRY ARTHROSCOPY

Preventing capsule collapse	■ The valve of the sheath of the scope should be open at all times for air to circulate within the joint; otherwise, the capsule will collapse inward when using suction, obstructing the view.
Limited use of suction	■ Open the suction only when needing to aspirate something, or debris may be stirred up that may stick to the tip of the scope.
Avoiding splashes	■ Avoid using the burs or osteotomes too close to the tip of the scope as minor splashes may block your vision. Minor splashes can be removed by gently rubbing the tip of the scope on the local soft tissue.
Clearing field with saline	■ When a clear field is needed, a syringe with 5–10 mL of saline may be connected to the side valve of the scope and then aspirated with an arthroscopic shaver to get rid of blood and debris. The negative pressure exerted by the shaver will suck the saline into the joint without any pressure on the plunger and prevent extravasation.
Preventing suction clog	■ Periodic saline aspiration from an external basin or by joint irrigation, and systematic joint flushing in some procedures (intercarpal arthrodesis, arthroscopic proximal carpectomy) during prolonged use of burs, which may cause heating of instrument and local burns

POSTOPERATIVE CARE

- Splinting:
 - Diagnostic: 4 to 7 days for comfort.
 - Arthroscopic reduction and scapholunate pinning: sugar-tong splint for 2 weeks, followed by short-arm cast for 8 weeks. Pins are removed at 10 weeks. Removable splint for 2 to 4 more weeks.
 - Open ligament repair with scapholunate pinning: sugar-tong splint for 2 weeks, followed by short-arm cast for 10 weeks. Pins are removed at 10 weeks. Removable splint for 2 to 4 more weeks.
 - TFCC debridement: volar resting splint for 2 weeks, and then begin range of motion exercises.
 - TFCC arthroscopic repair: sugar-tong splint for 2 weeks, followed by above-arm Munster cast for 4 weeks, followed by Munster splint until 45 degrees of nontender pronation and supination was achieved, and then volar resting wrist splint until full rotation achieved.
- Activity modification:
 - After splinting, gentle active range of motion of the wrist is encouraged. Gentle activities of daily living are resumed, but lifting is limited to less than 10 lb based on any repairs that have been performed.
 - Wrist capsule stiffness is a frequent complaint in postarthroscopy patients, and patient education is critical regarding active range of motion and duration of expected stiffness.
 - Gradual strengthening should be encouraged, and involvement of certified hand therapists can optimize recovery.

OUTCOMES

- TFCC tear diagnosis.
 - A recent retrospective review of 908 patients with arthroscopic-confirmed TFCC tears illustrated only a 0.53 to 0.55 positive predictive value of clinical tests and a positive predictive value of MRI of 0.41 to 0.44 in diagnosing a TFCC tear. Arthroscopy is the standard for diagnosing and staging TFCC tears.⁶
- Scapholunate ligament treatment
 - In partial SL ligament tears, 85% treated by arthroscopic debridement have reported satisfactory improvement in symptoms. Only 67% with complete tear reported satisfactory outcomes with debridement alone.⁷

- Arthroscopic reduction and K-wire pinning of SL instability is most beneficial in patients with instability for less than 3 months and a gap of 3 mm or less in the SL interval (83% symptomatic relief compared to 53% symptomatic relief if instability was present for longer, or a greater than 3-mm SL interval gap were present).⁸
- Lunotriquetral ligament treatment.
 - In a small series of LT ligament tears treated with arthroscopic debridement alone, 100% (six patients) with partial injury reported resolution of symptoms after debridement, and 78% (nine patients) with complete tear reported symptom resolution.⁷
- Wrist ganglion treatment
 - A systematic review of arthroscopically treatment volar wrist ganglions reported a recurrent rate of 0% to 20% (mean 6%) and a 7% complication rate. A higher complication rate was reported for arthroscopic treated of volar wrist ganglia in the midcarpal joint as the procedure is technically more difficult.⁹
- Fracture-reduction assistance
 - In case series of acute and nonunion scaphoid fractures, arthroscopy has been shown to aid in the assessment of fracture reduction.¹⁰ In acute scaphoid fractures, one series illustrated median time to union of 62 days and average return to work 21 days after surgery.¹⁰
 - A randomized-control trial of arthroscopically vs fluoroscopically assisted reduction of intra-articular distal radius fractures treated with volar locking plate illustrated no statistical difference in radiographic or functional outcomes, including range of motion (ROM) and disabilities of the arm, shoulder, and hand (DASH) scores, between the two groups.¹¹

COMPLICATIONS

- Most complications are related to injury of the dorsal cutaneous sensory nerve branches, particularly:
 - Superficial radial nerve in the 1-2 portal
 - Dorsal cutaneous branch of the ulnar nerve from the 6U portal
 - Palmar cutaneous branch of ulnar nerve from volar ulnar portal
 - Ulnar neurovascular bundle injury from over-retraction or poor portal placement
- Chondral injury from trochar insertion

- Venous bleeding
- Loss of wrist motion (particularly forearm supination)
- Fluid extravasation
- Infection
- Minor contact burns at the portals and dorsal skin by the full-radius resector and bur may occur in dry arthroscopy
- Meticulous technique is essential to reduce the above complications.

Ligament Reconstruction for Chronic Scapholunate Dissociation

15

CHAPTER

Mark Morris and Kevin C. Chung

DEFINITION

- Scapholunate instability is the most common form of carpal instability.
- Injury to the scapholunate interosseous ligament (SLIL) and subsequent dorsal intercalated segmental instability (DISI) results in scapholunate advanced collapse (SLAC) if untreated.¹
- Chronic tears generally require reconstruction rather than primary repair.
- Static vs dynamic instability²
 - Static instability: Any or all of the radiographic changes discussed below in the imaging section, seen on plain radiographs
 - Dynamic instability: Normal plain radiographs, but with stress radiographs, any or all radiographic changes are seen.
- Fixed vs reducible deformity
 - Fixed deformity: Static radiographic changes are not passively correctible.
 - Reducible deformity: Static radiographic changes are passively correctible.

ANATOMY

- The lunate, or the intercalated segment, is connected to the scaphoid via the scapholunate ligament and to the triquetrum via the lunotriquetral ligament.
- The scaphoid is inclined to flex, whereas the triquetrum is inclined to extend. Disruption in either ligamentous complex results in intercalated instability.
- The scapholunate ligament is a C-shaped structure that connects the dorsal, proximal, and volar surfaces of the scaphoid and lunate.³ It has three portions (**FIG 1**):
 - Dorsal portion

- 2 to 3 mm thick
- Greatest rupture strength and is responsible for rotational and translational restraint
- Proximal membranous portion
- Volar portion
 - 1 mm thick

PATHOGENESIS

- SLIL disruption occurs when the wrist is forced into extension, supination, and ulnar deviation.⁴
- SLIL injuries range from sprains, partial tears, or complete tears.
- The SLIL usually fails at the scaphoid bone-ligament interface.

NATURAL HISTORY

- With complete rupture of the SLIL, the scaphoid flexes and the lunate is now free to be pulled into extension either by the triquetrum⁵ or because of its own natural tendency due to its shape.⁶ This produces the DISI pattern.
- Left untreated, the DISI deformity results in abnormal radiocarpal contact.
- Flexion and hypermobility of the scaphoid leads to a predictable pattern of degenerative changes, resulting in SLAC wrist.
- SLAC was initially described in three stages but has been more recently described in five stages of degenerative changes:
 - Stage I: radioscapoid
 - Stage II: scaphocapitate
 - Stage III: lunocapitate
 - Stage IV: triquetrohamate
 - Stage V: radiolunate

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients complain of radial-sided wrist pain exacerbated by loading activities, weak grip, swelling, and loss of wrist range of motion.
- Tenderness to palpation in the anatomic snuffbox or over the scapholunate interval, just distal to Lister tubercle
- Pain with extremes of wrist extension and radial deviation
- Diminished grip strength on examination
- Watson scaphoid shift test may be positive in scapholunate dissociation (**FIG 2**).⁷

- The examiner places his or her thumb over the scaphoid tuberosity and the fingers over the dorsal radius. The other hand is used to move the wrist passively from ulnar to radial deviation. The scaphoid is extended with the wrist in ulnar deviation and flexed with the wrist in radial deviation. The examiner applies pressure on the scaphoid tuberosity while moving the wrist from ulnar to radial deviation. This prevents the scaphoid from flexing. If the SLIL is completely torn, the proximal pole subluxes dorsally out of the scaphoid fossa, inducing pain on the dorsoradial aspect of the wrist. When pressure is released, a clunk may occur. This indicates self-reduction of the scaphoid back into its normal position.
- Scapholunate ballottement test may also be positive.
 - The examiner holds the patient's scaphoid between the thumb and index finger. The thumb is placed over the tuberosity, and the index finger is placed over the proximal pole. The thumb and index fingers of other hand are used to hold the lunate. The examiner attempts to move the scaphoid and lunate in opposite directions.
 - This test is positive when it elicits pain.

FIG 1 • The scapholunate ligament is a C-shaped

structure that consists of a stronger dorsal portion (2–3 mm thick), a proximal membranous portion, and a volar ligamentous portion (1 mm thick).

IMAGING

- Radiographs may demonstrate the following findings suggestive of SLIL injury:
 - Terry Thomas sign: Scapholunate diastasis of more than 3 mm on standard PA radiographs (**FIG 3A**)⁸
 - Signet ring sign: The presence of a flexed scaphoid on standard PA radiographs produces a cortical hyperdensity that resembles a signet ring (see **FIG 3A**).⁵
 - Angular changes in the carpal bones
 - The normal scapholunate angle ranges from 30 to 60 degrees. An angle over 60 degrees is seen with SLIL injury (**FIG 3B**).
 - The normal capitolunate angle ranges from –15 to 15 degrees. An angle greater than 15 degrees is seen with SLIL injury.
 - The normal radiolunate angle ranges from –10 to 10 degrees. An angle greater than 10 degrees is seen with SLIL injury.

FIG 3 • A. PA radiograph of the wrist showing diastasis of the scapholunate interval (*arrow*). A signet ring sign can also be seen here (*circled*), which is produced when the scaphoid is flexed so the tubercle is superimposed on the waist of the scaphoid. **B.** The scapholunate angle is formed by the intersection of the scaphoid axis (a line drawn between the most palmar point of the distal pole and the most palmar point of the proximal pole) and the lunate axis (a line drawn perpendicular to a line drawn between the most distal palmar and dorsal points of the lunate). A scapholunate angle greater than 70 degrees indicates a DISI deformity.

- Quadrangular lunate: The lunate appears rectangular on standard PA radiographs as it moves into extension.

- Disruption of Gilula lines as the relationship of the proximal carpal row is lost.
- The presence of degenerative changes involving the radiocarpal or midcarpal joints is a contraindication for ligament reconstruction.

FIG 2 • Watson scaphoid shift test. The examiner uses his or her thumb to apply pressure over the scaphoid tuberosity while using the other hand to move the wrist from ulnar to radial deviation.

- MRI can be performed to identify tears when radiographs are normal.
- The sensitivity of a 3-T MRI ranges from 65% to 89% for complete scapholunate ligament tears. The sensitivity of MRA is reported to be 85% to 100%.
- The sensitivity of both MRI and MRA is poor for partial ligament tears.⁸

DIFFERENTIAL DIAGNOSIS

- Partial SLIL tear

- Radiocarpal arthritis
- Scaphoid fracture
- Keinbock disease

NONOPERATIVE MANAGEMENT

- Nonoperative management of complete SLIL tear is unsuccessful and reliably results in radiocarpal and midcarpal degenerative changes.

SURGICAL MANAGEMENT

- Direct repair is rarely an option for a chronic SLIL tear.
- Capsulodesis is an option for dynamic scapholunate dissociation if secondary stabilizers are intact and there is no cartilage degeneration. Capsulodesis is not indicated in the case of static scapholunate dissociation.
- Ligament reconstruction

Preoperative Planning

- The surgeon can consider diagnostic wrist arthroscopy prior to ligament reconstruction. This will help to better characterize the articular surfaces of the carpal bones, as well as to better delineate the degree of ligament injury.

Positioning

- The patient is positioned supine on the operating table. The operative extremity is draped out on a hand table.
- We prefer to use regional anesthesia for this operation. General anesthesia can also be used.
- A tourniquet is applied.
- An examination under anesthesia is performed. A Watson shift test is done to feel for a clunk.

Approach

- Volar and dorsal incisions are made.
- The volar incisions are used to harvest the flexor carpi radialis (FCR) graft.
- The dorsal incision is used for most of the reconstruction.

TECHNIQUES

■ Exposure

■ Dorsal

- An 8-cm longitudinal dorsal wrist incision is centered over Lister tubercle (**TECH FIG 1A**).
- The extensor retinaculum over the third compartment is opened, and the extensor pollicis longus (EPL) is retracted radially.
- The dorsal wrist capsule is opened through a longitudinal incision to expose the scapholunate interval (**TECH FIG 1B**).

TECH FIG 1 • **A.** Dorsal wrist incision. **B.** The scapholunate interval is exposed. The Freer elevator in this image is in the scapholunate interval. **C.** Volar wrist incisions.

■ Volar

- Three 1-cm incisions are made along the course of the flexor carpi radialis (FCR; **TECH FIG 1C**).
- An oblique Wagner incision is made over the scaphoid tuberosity.
- The radial sensory nerve is at risk with this incision and must be preserved.
- The scar tissue is excised between the scaphoid and lunate.

■ Reduction of Scaphoid and Lunate and Creation of a Bone Tunnel

- Two 0.062-inch K-wires are placed dorsally into the scaphoid and lunate. The K-wires are used as joysticks to aid in reduction (**TECH FIG 2**).
 - Threaded wires may provide better purchase of the scaphoid and lunate so joystick wires do not pull out.
- Wires must be drilled away from the anticipated tunnel for the planned ligament reconstruction.
- To correct the DISI deformity, the surgeon must extend the scaphoid and flex the lunate. Direct the scaphoid wire proximally and the lunate wire distally.
- To create a bone tunnel, a K-wire is passed from the scaphoid tuberosity to the dorsum of the scaphoid along its axis.
- A cannulated 2.7-mm drill is passed over the wire from the dorsum to the palmar side.

Harvesting and Passing a Strip of Distally Based FCR Tendon

- A distally based 3-mm-wide by 8- to 10-cm-long strip of FCR tendon is harvested from the radial aspect of the tendon (**TECH FIG 3**).

TECH FIG 2 • A. K-wires are used for reduction of the scaphoid and lunate. **B.** The scaphoid wire is directed proximally to extend the scaphoid (*solid arrow*), whereas the lunate wire is directed distally to flex the lunate (*dashed arrow*).

TECH FIG 3 • The distally based FCR tendon graft is harvested and passed through the scaphoid tunnel.

- The FCR tendon rotates 90 degrees within the sheath at the wrist. It is important to follow the fibers so the tendon is not inadvertently transected. Do not slide the scissors through the tendon fibers; cut along the fibers to maintain the integrity of the tendon.
- A grasping suture is placed at the cut end of the distally based FCR tendon and is then passed through the scaphoid tunnel from volar to dorsal.
- Forcing a wide strip of FCR through the scaphoid tunnel can fracture the scaphoid. It is better to harvest a narrow strip of FCR tendon.

Reduction of the Scapholunate Interval

- The scapholunate interval is reduced using the joystick K-wires. The K-wires can only correct the flexion-extension deformities of the scaphoid and lunate. A bone reduction clamp or towel clip is used to reduce the gap between the two bones.
- Reduction is maintained by passing new K-wires across the scapholunate and scaphocapitate joints.
- Confirm reduction of the scapholunate interval with fluoroscopy. Once this is done, the joystick K-wires can be removed.

Securing the FCR to the Lunate and Closure

- A bur is used to make a shallow trough on the dorsum of the lunate.
- The FCR tendon graft is secured to the midportion of the trough using a 1.8-

mm bone anchor suture (**TECH FIG 4A**).

- The remaining portion of the tendon graft is passed through a slit in the distal portion of the dorsal radiotriquetral ligament and is sutured back to itself over the lunate (**TECH FIG 4B**).
- The dorsal capsule is first repaired using 3-0 Ethibond suture.
- The tourniquet is released and hemostasis is obtained.
- The EPL is transposed dorsal to the extensor retinaculum to avoid ischemic rupture that may occur due to postoperative swelling in the EPL sheath. The extensor retinaculum is also closed using 3-0 Ethibond suture.
- Skin is closed using 4-0 nylon suture.

TECH FIG 4 • A. The FCR tendon is secured into the trough in the lunate using a 1.8-mm bone anchor suture. **B.** The remaining FCR tendon graft is sutured back over itself.

PEARLS AND PITFALLS

- Technique**
- Some authors recommend a ligament-sparing capsulotomy to expose the scapholunate interval. To do so, the capsular incision is made in

line with the fibers of the intercarpal and radiocarpal ligaments, and a trapezoid capsular flap is raised.

- The superficial radial nerve and palmar cutaneous branch of the median nerve are at risk with the volar portion of the surgery and should be identified and protected.
- The FCR tendon can be inadvertently transected as it rotates 90 degrees at the wrist. Be careful and follow the fibers rather than blindly sliding the scissors to harvest the graft.
- The scaphoid can be fractured if the surgeon attempts to force a wide graft through the tunnel. The tendon graft should be approximately 3 mm wide.
- K-wires are cut under the skin to avoid pin tract infection. The K-wires are removed in the operating room in 8 wk.

Therapy

- In therapy, initial restriction of radial and ulnar deviation lessens the force on the SLIL ligament reconstruction.

POSTOPERATIVE CARE

- The patient is placed in a volar wrist splint postoperatively.
- The splint and operative dressings are taken down after 10 to 14 days, and the wound is examined. Sutures are removed at this time.
- The patient will remain splinted for 8 weeks.
- After 8 weeks of splinting, the patient is transitioned to a removable volar wrist splint for an additional 4 weeks. Gentle active wrist range of motion is started at this time. We do not send the patient to therapy because injudicious stressing of the wrist to get more motion will disrupt the reconstruction. Our goal is painless motion and whatever motion the patient can achieve is the suitable motion. This expectation must be presented to the patient before surgery; we inform the patient that there is no good wrist operation and all wrist operations trade pain relief for decreased wrist motion.
- Initial restriction of radial and ulnar deviation lessens the force on the ligament reconstruction.
- K-wires are removed 6 to 8 weeks after surgery.

OUTCOMES

- Most patients will have mild to no pain after initial recovery from surgery.^{9–12}
- Most patients feel subjective improvement and would have the operation again.⁹
- Studies have shown a slight loss of wrist motion after surgery (**FIG 4**).

- Total wrist motion averaged 85% of contralateral (uninjured) wrists in one study at an average of 10 years of follow-up.¹¹
- A more recent study of 20 patients with a mean follow-up of 24 months showed that wrist flexion was reduced by a mean of 19 degrees, and extension was decreased by a mean of 14 degrees.¹²

FIG 4 • Five-month postoperative clinical photographs after scapholunate ligament reconstruction with FCR tendon autograft. This patient demonstrates a minor loss of motion of the operative (**left**) wrist, as is to be expected. This loss of motion did not cause him any discomfort or disability. He was very satisfied with his outcome.

- Radial and ulnar wrist deviation has been shown to be 68% and 86% of contralateral wrists, respectively, in one study and equal to contralateral in another.^{9,10}
- Grip strength has been shown to be 78% to 85% of contralateral (uninjured) strength after a modified Brunelli reconstruction.^{10–12}
- Radiographic parameters improve after surgery. In one study, the average

preoperative scapholunate gap was 5.1 mm, which was reduced to 2.4 mm at surgery and was 2.8 mm at final follow-up at an average of 10 years.¹¹

Scapholunate angle has been shown to improve to within normal limits immediately after surgery but may increase again after longer follow-up.¹⁰⁻¹²

- Most patients avoid degenerative changes of the wrist.¹⁰⁻¹²

COMPLICATIONS

- Damage to superficial radial nerve or the palmar cutaneous branch of the median nerve.
- Scar tenderness.⁹
- Complex regional pain syndrome.^{9,10}
- SLAC wrist occurred in 1 out of 19 patients in one study with a mean of 37 months of follow-up,¹⁰ 1 out of 8 in another study with a mean of 10 years of follow-up,¹¹ and 3 out of 20 in another study with a mean of 24 months of follow-up.¹²
- Ligament reconstruction should not be performed in patients who already have degenerative changes on radiographs.

Lunotriquetral Ligament Reconstruction Using a Slip of the Extensor Carpi Ulnaris Tendon

16

CHAPTER

Mark Morris and Kevin C. Chung

DEFINITION

- Isolated injury to the lunotriquetral (LT) ligament is less common than injury to the scapholunate (SL) ligament.
- LT ligament injury can be found in isolation or in combination with other injuries, such as in the case of a perilunate dislocation.
- The mechanism of LT ligament injury is debated but may be secondary to a dorsally applied force to a palmar-flexed wrist. Perilunate dislocation is thought to occur when the wrist is forced into hyperextension and ulnar deviation.¹
- LT disruption can be the result of acute trauma or secondary to degenerative or inflammatory conditions.
- LT injury ranges from partial tears to complete dissociation. Partial tears or attenuation of the ligament are more common and result in dynamic instability, whereas complete dissociation leads to static collapse.
- Volar intercalated segment instability (VISI) occurs after complete disruption of the LT ligament, dorsal radiotriquetral ligament, and volar radiolunate ligament.
- VISI may occasionally be seen in uninjured wrists, in contrast to dorsal intercalated segment instability (DISI), which is always pathologic.

ANATOMY

- The LT ligament is C-shaped, consisting of dorsal, proximal membranous, and

palmar portions (**FIG 1**). In contrast to the SL ligament where the dorsal portion is thickest and strongest, the palmar region of the LT ligament is the thickest and strongest portion.^{2,3}

- Secondary stabilizers of the LT joint include the ulnocarpal (ulnolunate, ulnocapitate, and ulnotriquetral), midcarpal (triquetrohamate and triquetrocipitate), and dorsal carpal (dorsal intercarpal and radiotriquetral) ligaments (**FIG 2**).
- Complete tear of only the LT ligament will not result in VISI deformity because the secondary stabilizers maintain the lunate and triquetrum in position.
- The scaphoid has a tendency to flex, whereas the triquetrum has a tendency to extend. The lunate, or intercalated segment, is balanced by these two opposing forces.

PATHOGENESIS

- Isolated LT tear is thought to occur when a dorsally applied force is applied to a palmar-flexed wrist. This force causes the dorsal LT fibers to tear. The volar radiolunate ligaments remain intact and tether the proximal lunate on the volar side, leading to palmar flexion.
- Reverse perilunate injuries occur from falling on an outstretched hand with the wrist extended, pronated, and radially deviated. This mechanism can also result in an isolated LT tear, followed by lunocapitate dislocation, and then SL dissociation (**FIG 3A**).⁴
- Perilunate injuries occur when the wrist is forced into hyperextension and ulnar deviation. Mayfield describes four stages of perilunate injury (**FIG 3B**).¹ LT injuries occur in Mayfield III and IV perilunate injuries.
- Inflammatory arthritis or degenerative LT lesions may also lead to instability.

NATURAL HISTORY

- The natural history of LT injuries has not been clearly defined; however, they may lead to degenerative changes of the wrist.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients present with ulnar-sided wrist pain.
- Patients may or may not report a history of trauma.
- Patients may have tenderness to palpation over the dorsal LT joint.

FIG 1 • The lunotriquetral ligament is C-shaped, consisting of palmar, dorsal, and proximal membranous portions. The palmar portion is the thickest and strongest portion of the ligament.

FIG 2 • A. Dorsal wrist ligaments. The important dorsal secondary stabilizers of the lunotriquetral joint are the dorsal intercarpal and dorsal radiotriquetral (also known as dorsal radiocarpal) ligaments. **B.** Volar wrist ligaments. The important volar secondary stabilizers of the lunotriquetral joint are the short and long radiolunate ligaments, the ulnolunate ligament, the ulnocapitate ligament, and the ulnotriquetral ligament.

- LT compression test: Radially directed pressure is applied over the triquetrum. This may elicit pain in patients with LT instability (**FIG 4A**).
- LT ballottement test: The lunate is stabilized with the thumb and index finger of one of the examiner's hands. The other hand is used to displace the triquetrum and pisiform dorsally and palmarly. Pain, crepitus, and joint laxity are seen in patients with LT instability (**FIG 4B**).
- Ulnar deviation with pronation and axial compression may elicit instability and a painful clunk.
- Limited range of wrist motion
- Diminished grip strength

IMAGING

- A PA radiograph may show a break in Gilula lines. There is often a step-off between the lunate and triquetrum.

- It is rare to see a gap in the LT interval on radiographs with LT injuries, in contrast to SL injuries where a gap is seen. Plain radiographs may be normal (**FIG 5**).

FIG 3 • A. Reverse perilunate injuries start on the ulnar side of the wrist starting with an isolated LT tear, followed by lunocapitate dislocation, and then scapholunate dissociation. **B.** Mayfield's four stages of perilunate injury. Stage 1: Disruption of scapholunate ligament or scaphoid fracture. Stage 2: Lunocapitate dislocation. Stage 3: Lunotriquetral dissociation or triquetrum fracture. Stage 4: Lunate dislocation.

FIG 4 • A. Lunotriquetral compression test. The examiner applies radially directed pressure over the triquetrum. **B.** Lunotriquetral ballottement test. The lunate is stabilized with the thumb and index finger of one of the examiner's hands. The other hand is used to displace the triquetrum and pisiform dorsally and palmarly.

- A lateral radiograph may show a VISI deformity, marked by volar tilting of the lunate. This indicates injury to the LT injury along with injury to the dorsal radiotriquetral ligament (**FIG 6**).
- The SL angle is less than 30 degrees with a VISI deformity.
- The capitolunate angle increases to over 15 degrees with a VISI deformity.
- MRI is not reliable for imaging of LT ligament injuries.

DIFFERENTIAL DIAGNOSIS

- Ulnar impaction syndrome
- Distal radioulnar joint instability
- Extensor carpi ulnaris subluxation

- Triangular fibrocartilage complex injuries
- Pisotriquetral arthritis
- Hook of hamate fracture

FIG 5 • PA, oblique, and lateral radiographs of a patient with a lunotriquetral injury. There is no apparent widening of the lunotriquetral interval or VISI deformity seen here; however, a lunotriquetral ligament tear was found on wrist arthroscopy after the patient failed nonoperative management.

FIG 6 • The VISI deformity is marked by the lunate in a flexed position, which decreases the scapholunate angle and increases the capitolunate angle.

NONOPERATIVE MANAGEMENT

- The appropriate management of an acute LT injury is immobilization in a cast for 8 to 12 weeks. Patients who present with subacute or chronic LT injuries should also be treated first with immobilization, but the timing is less well-defined and can be determined by the patient's symptoms during immobilization.⁵
- Midcarpal injections with local anesthetic and corticosteroids may be a helpful adjunct to immobilization.

SURGICAL MANAGEMENT

- Surgical management is indicated in patients with symptomatic LT

dissociation that is not relieved by nonoperative management.

- The goal of surgery is to restore stability to the proximal carpal row and to realign the lunocapitate axis.

FIG 7 • A dorsal wrist incision is used, centered between the fourth and fifth compartments.

- Ligament reconstruction should be reserved for patients without arthritic changes.
- If degenerative changes are already present, the surgeon should consider arthrodesis or proximal row carpectomy.

Preoperative Planning

- The surgeon can consider diagnostic wrist arthroscopy prior to ligament reconstruction. This will help to better characterize the articular surfaces of the carpal bones, as well as to better delineate the degree of ligament injury.

Positioning

- The patient is positioned supine on the operating table. The operative extremity is draped out on a hand table.
- We prefer to use regional anesthesia for this operation. General anesthesia can also be used.
- A tourniquet is applied.
- An examination under anesthesia is performed to evaluate for a clunk. The distal radioulnar joint can be assessed under anesthesia as well.

Approach

- A 6-cm longitudinal incision is used, centered over the dorsal wrist between the fourth and fifth compartments (**FIG 7**).
- Alternatively, two incisions can be used—one incision over the dorsal wrist joint, and another proximally over the ECU tendon harvest site.

TECHNIQUES

■ Exposure and Tendon Harvest

- A longitudinal skin incision is centered over the dorsal wrist, between the fourth and fifth compartments.
- The wrist capsule is incised longitudinally (**TECH FIG 1A,B**). The LT interval should now be visible (**TECH FIG 1C,D**).
- Excise scar tissue from between the lunate and triquetrum.
- The ECU tendon is identified in the proximal portion of the incision.
- A distally based slip of ECU tendon is harvested from the radial aspect of the tendon (**TECH FIG 1E,F**).
- The tendon graft should be 3 mm wide by 8 to 10 cm long.
- The strip of tendon graft is dissected to its insertion at the base of the small finger metacarpal.

TECH FIG 1 • A,B. Longitudinal incision of the wrist capsule. **C,D.** The lunotriquetral interval is shown here with a Freer elevator. The lunotriquetral ligament here is ruptured. **E.** The intact ECU tendon (*arrow*). **F.** A 3-mm strip of distally based ECU tendon is harvested.

■ Reduction of the Lunate and Triquetrum and

Creation of Bone Tunnels

- Two 0.062-in. Kirschner wires (K-wires) are inserted into the dorsal lunate and triquetrum to be used as joysticks for reduction (**TECH FIG 2A**). Be sure to keep the K-wires out of the way of the planned tunnels in each bone.
- To correct the VISI deformity, the lunate is extended by retracting the lunate K-wire proximally and the triquetrum is flexed by retracting the triquetral K-wire distally.
- To create the bone tunnels, a K-wire is placed in the triquetrum from the distal, dorsal, ulnar aspect toward the proximal, palmar, radial corner. Once acceptable placement is confirmed, a 2.5-mm cannulated drill is used to create a bone tunnel in the triquetrum over the K-wire (**TECH FIG 2B,C**).
- The lunate bone tunnel is then created in similar fashion by placing a K-wire from the distal, dorsal, and radial corner of the lunate to the proximal, palmar, and ulnar corner. A cannulated drill is again used over the K-wire to form the tunnel.
- The tunnels should converge at the volar margin of the LT joint and should remain extra-articular.

TECH FIG 2 • **A.** Joystick K-wires are placed into the triquetrum and lunate. The *arrows* show the direction of retraction required to reduce the VISI deformity. **B.** A bone tunnel is created in the triquetrum (T) using a cannulated drill. **C.** A microcurette is used to clear cartilage remnants at the exit sites of the tunnels.

■ Passing and Securing the ECU Tendon Graft

- The tendon is passed through the bone tunnels using a wire or suture. First pass the tendon from the dorsum of the triquetrum to the LT interval and then from the LT interval to the dorsum of the lunate (**TECH FIG 3A**).
- Alternatively, after passing the graft through the triquetrum, a small bone anchor can be used to secure the tendon graft to the lunate (**TECH FIG**

3B,C). The VISI deformity must be corrected with the joystick K-wires prior to fixation with an anchor.

- Next, the ECU graft is secured to itself over the remnant of the LT ligament.

TECH FIG 3 • A. Bone tunnels are made through the triquetrum and lunate. A wire or suture (pictured) is used to feed the graft through the bone tunnels. **B,C.** A mini-Mitek anchor can be used to fix the graft to the lunate. **D,E.** One or two K-wires are inserted to hold the reduction of the lunotriquetral joint. Here, an additional wire was placed through the triquetrum into the hamate and capitellum. **F.** After passing the tendon graft through the triquetrum and lunate, the free end is sutured back to itself.

- First, the VISI deformity is corrected as described earlier with the joystick K-wires.
- The corrected position is held with a third K-wire passed through the triquetrum and lunate (**TECH FIG 3D,E**). The triquetrum should also be pinned to the capitate to fixate the reduced construct; otherwise, the triquetrum may rotate around the single K-wire to lose the reduction.
- The end of the tendon graft is then sutured back to itself using 3-0 Ethibond sutures (**TECH FIG 3F**).

■ Closure

- The wrist capsule is closed tightly with 3-0 Ethibond suture.
- The extensor retinaculum over the fourth and fifth compartments is closed using 3-0 Ethibond suture.
- The joystick K-wires are removed at this time.
- The K-wire traversing the LT joint is left in place and is cut deep to the skin. This is done to avoid pin tract infections from a pin that will be left in place.

PEARLS AND PITFALLS

Technique

- Branches of the dorsal ulnar sensory nerve should be protected. The dorsal sensory branch of the ulnar nerve arises 8 cm proximal to the pisiform and passes dorsal to the FCU and pierces the fascia 5 cm proximal to the pisiform. It reaches the dorsal hand in close proximity to the ulnar styloid process.
- The ECU tendon graft should not be more than 3 mm wide. If it is too wide, it will be difficult to pass through the drill holes in the lunate and triquetrum.
- Joystick K-wires are used to correct the VISI deformity. The lunate wire is placed obliquely from a distal to proximal direction, and the triquetral wire is placed from an oblique proximal to distal direction. The VISI deformity is corrected by making both wires perpendicular to the axis of the forearm.
- An alternative technique to drilling bone tunnels is to use a sharp curved awl. This is less traumatic and may help to avoid fracturing the carpal bones.

- Ulnar shortening osteotomy may be performed at the same time as LT ligament reconstruction in a patient with concomitant ulnocarpal abutment.

Postoperative

- Pain is significantly improved in most patients after this procedure.

Therapy

- Do not be too aggressive with therapy or the repair can fail. Long-term satisfaction is high even though patients do typically lose some wrist range of motion.

POSTOPERATIVE CARE

- The patient is placed in a volar wrist splint immediately postoperatively.
- Incisions are examined and sutures are removed after 10 to 14 days.
- The patient is kept in a volar wrist splint for 8 weeks.
- K-wires are removed after 8 weeks.
- The patient can start gentle range of motion exercises after K-wires are removed. Wrist stiffness is common (**FIG 8**).

FIG 8 • Six-month follow-up after lunotriquetral ligament reconstruction. Although the patient lost some wrist range of motion, he was satisfied with his result.

OUTCOMES

- Shin et al.⁶ demonstrated that patients who had LT ligament reconstruction had lower reoperation rates than did patients treated with direct repair or arthrodesis.
- Shahane et al.⁷ studied 46 patients who underwent LT ligament reconstruction with ECU tendon. After a mean of 19 months of follow-up, 19 patients (41%) had excellent outcomes, 10 (22%) had good outcomes, 11 (24%) had satisfactory outcomes, and 6 (13%) had poor outcomes based on Mayo wrist scores. Forty of 46 patients said that they had substantially improved and would undergo the operation again.

COMPLICATIONS

- Injury to the dorsal branch of the ulnar nerve
- Pisotriquetral pain
- Reflex sympathetic dystrophy
- Residual instability

17 Fixation of Acute Scaphoid Fractures

CHAPTER

Ketan Sharma, James T. W. Saunders, and Amy M. Moore

DEFINITION

- The scaphoid is the most commonly fractured bone of the carpus.
- *Acute* scaphoid fractures are defined as occurring within 3 to 4 weeks of the inciting event.
- *Displaced* scaphoid fractures are defined as exhibiting more than 1 mm displacement or more than 10 degrees angulation.
- Operative treatment of acute scaphoid fractures remains challenging due to the complex geometry and tenuous blood supply of the scaphoid itself.
- Herbert's system classifies fractures into four types¹:
 - Type A—stable and acute
 - Type B—unstable and acute
 - Type C—delayed unions
 - Type D—established nonunion

ANATOMY

- The scaphoid spans the proximal and distal carpal rows, and serves as an important dynamic link between the two.
- The scaphoid articulates with the radius, lunate, capitate, trapezoid, and trapezium.
 - These numerous articulations mean that over 80% of the surface area of the scaphoid is covered with cartilage and not periosteum.
 - This characteristic limits both ligamentous structural integrity and vascular healing potential.
 - This also means the scaphoid heals predominantly through primary bone healing (intramembranous ossification), which can result in a paucity of

callus formation and weak early union.²

- The scaphoid bone is divided into three regions: the proximal pole, waist, and distal pole (or tubercle [**FIG 1**]).
- The proximal pole of the scaphoid articulates with the distal radius within the scaphoid fossa, and is coupled to the neighboring lunate within the proximal row via the strong scapholunate (SL) ligament.
 - This ligament prevents the scaphoid from falling into a flexed position, and is crucial for carpal stability.
- Vascular supply to the scaphoid is provided through two main branches of the radial artery (**FIG 2**).
 - The dorsal branch supplies 70% to 80% of the total vascularity, enters at the dorsal ridge distally, and supplies the entire proximal pole.

FIG 1 • **A.** PA (**B**) and lateral radiographs showing nondisplaced fracture of the scaphoid waist (scaphoid

outlined in *yellow*; fracture magnified in inset in **A**). The scaphoid is divided into three regions (proximal pole, waist, distal pole) and serves as an important dynamic link between the proximal and distal carpal rows.

FIG 2 • The scaphoid is supplied by dorsal and volar branches of the radial artery, which predominantly distribute to the proximal and distal poles, respectively. This unique retrograde vasculature has important implications concerning healing of waist and proximal pole fractures.

- The volar branch supplies 20% to 30% of the total vascularity, enters through the tubercle, and supplies the distal pole and distal tuberosity predominantly.³
- The proximal pole receives the majority of its blood supply through retrograde intraosseous vascular flow from these arteries and is therefore susceptible to avascular necrosis (AVN) when this supply is disrupted by the fracture.

PATHOGENESIS

- The most common mechanism of injury of the scaphoid is a hyperextension of the wrist more than 95 degrees, coupled with an ulnar deviation.⁴
- A volar tensile force leads to failure and propagation of a fracture through the body of the scaphoid to the dorsal surface where compression loading occurs.
- Impingement on the dorsal rim of the distal radius during hyperextension may also contribute to waist fractures.
- Proximal pole scaphoid fractures likely occur from dorsal subluxation during forced hyperextension.
- Less commonly, hyperflexion and axial loads may also produce scaphoid fractures.

NATURAL HISTORY

- The natural history of scaphoid fractures remains integral to treatment strategy.
- Healing potential is fundamentally a function of fracture potential and available vascularity.
 - More proximal fractures have poorer blood supply, leading to decreased healing potential, which can produce nonunion or AVN.
 - Fracture displacement disrupts the blood supply and decreases healing potential.
- Fractures displaced more than 1 mm or angulated more than 15 degrees have an increased risk of nonunion.
- Displaced or untreated scaphoid nonunions will predictably progress to dorsal intercalated segmental instability (DISI) type carpal instability, and eventually scaphoid nonunion advanced collapse (SNAC) arthrosis.
 - In patients with a nonunion, up to 97% will demonstrate arthritic change within 5 years of the injury.⁵
- Risk factors for scaphoid nonunion include delayed treatment, inadequate immobilization, proximal fractures, comminution, and concomitant carpal injuries.⁶

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with acute or subacute scaphoid fractures typically present with a history of a high-energy fall or a wrist hyperextension–type injury.
- Patients present with radial-sided wrist pain, swelling, and loss of range of motion (ROM), most predominantly on dorsiflexion.
- Physical examination signs include the following:
 - Wrist edema over the dorsal/radial aspect of the wrist (occasionally accompanied by ecchymosis)
 - Pain on active or passive extension of the wrist localized to the dorsal/radial aspect
 - Focal pain on palpation within the anatomic snuffbox (space between the first and third extensor compartments at the level of the wrist). Always compare to the contralateral side as this is inherently a tender area.
 - Pain on palpation of the scaphoid tubercle volarly
 - Dorsal/radial wrist pain on resisted extension of the second digit
 - Decreased ROM of the wrist
 - Pain on axial loading of the wrist (scaphoid compression test)

IMAGING

- Radiographs should be obtained on any patient suspected of having a scaphoid fracture.
 - Dedicated scaphoid views should be achieved with the wrist in ulnar deviation, an oblique view, a PA view, a lateral view, and a clenched fist view (allows assessment of dynamic instability of the scapholunate ligament).
 - Approximately 25% of scaphoid fractures are not visible on initial radiographs, posing a diagnostic barrier.
 - Any patient with a high clinical probability of scaphoid injury but a negative plain film series either should be splinted for 10 to 12 days before obtaining repeat films or should undergo more sensitive additional imaging (CT or MRI).
- CT scans taken in the axis of the scaphoid offer additional information regarding the architecture or displacement and have utility in diagnosing acute fractures not seen on plain films. They are also useful in assessing for bony union or nonunion after treatment has been initiated (**FIG 3**).
- MRI is helpful in identifying occult fractures in the acute setting. The addition of gadolinium, as a contrast agent, can be used to assess the vascularity of the proximal pole if there are concerns of AVN.

FIG 3 • A. Coronal and **(B)** sagittal CT slices showing a nondisplaced comminuted fracture of the scaphoid waist. Preoperative CT scans can provide additional diagnostic utility especially concerning degree of comminution, and postoperative scans can also allow for superior evaluation of malunion or nonunion. S, scaphoid; L, lunate; Rs, radius; Ua, ulna; C, capitate; H, hamate; Tq, triquetrum; Td, trapezoid; Tm, trapezium; R, radial; U, ulnar; V, volar; D, dorsal.

- A displaced/unstable scaphoid fracture is defined as:
 - Cortical displacement 1 mm or greater
 - More than 10 degrees of angular displacement
 - Comminution at the fracture site
 - Radiolunate angle of more than 15 degrees
 - Scapholunate angle of more than 60 degrees
 - Intrascaphoid angle of more than 35 degrees

DIFFERENTIAL DIAGNOSIS

- Wrist sprain
- Distal radius fracture
- Fracture of other carpal bones
- Ligamentous injury (most commonly, SL)
- Preiser disease (spontaneous AVN of the scaphoid)

NONOPERATIVE MANAGEMENT

- Nonoperative management, in the form of cast immobilization, is effective only in low-risk scaphoid fractures that meet all of the following criteria:
 - Acute fractures (less than 4 weeks old)
 - Nondisplaced
 - Favorable location (distal pole)
- Nondisplaced fractures of the scaphoid waist remain controversial regarding operative vs nonoperative treatment.
 - Nondisplaced waist fractures can be treated nonoperatively with immobilization for 10 to 12 weeks with close follow-up, with union rates as high as 90% in this scenario.¹
 - Patients with a nondisplaced scaphoid waist fracture who wish to mobilize early (highly active persons, athletes, manual workers, or those in high-demand occupations) should undergo operative fixation.
- Nondisplaced and displaced fractures of the proximal pole should be surgically managed to minimize the risk of AVN.
- Splint or cast immobilization should immobilize at least the wrist and thumb CMC but does not need to include the entire thumb.⁷ Above-elbow casting is not needed.
- Nondisplaced distal pole fractures have a high rate of union after cast immobilization for 6 to 8 weeks.
- Union, especially for conservatively treated scaphoid waist fractures, should be assessed with a CT scan to assess for bony bridging at approximately 8 to 10 weeks after the injury.

SURGICAL MANAGEMENT

- Surgical management is best for fractures that are unstable or displaced.
- An open approach is indicated for⁸ the following:
 - Proximal pole fractures
 - A displaced, unstable fracture of the scaphoid waist
 - Associated carpal instability or perilunate instability
 - Associated distal radius fracture. Both fractures can be addressed at one operative time and will allow for early mobility.
- A percutaneous approach is indicated for the following:
 - Nondisplaced fractures of the scaphoid waist
 - A displaced fracture of the scaphoid waist

- Proximal pole fractures
- Percutaneous fixation is technically difficult and has not been shown to have better outcomes. Thus, the authors advocate for an open approach to the scaphoid.
- Both percutaneous and open procedures can be performed from the volar or dorsal approach depending on fracture characteristics.
- In general, fractures of the proximal pole are approached dorsally to allow for antegrade screw fixation and compression across the fracture. This approach maximizes the amount of screw threads distally.
- Scaphoid fractures with associated carpal instability are also approached dorsally to allow for adequate exposure of the proximal carpal row. A K-wire can be placed in the lunate to assist reduction of the proximal scaphoid pole via its attachment through the scapholunate ligament. This assists obtaining and maintaining carpal realignment with scaphoid screw fixation.
- Approaching scaphoid waist fractures, which have a tendency to flex volarly at the fracture site, from the dorsal approach makes reduction more challenging, as the wrist must be flexed to bring the axis of the scaphoid above the dorsal lip of the distal radius. In these cases, a volar approach can be used.

Preoperative Planning

- Imaging studies should be thoroughly reviewed to confirm fracture geometry.
- Required equipment includes
 - K-wires
 - Portable mini-fluoroscopy (“mini C-arm”)

FIG 4 • A. The patient should be positioned supine, with the shoulder abducted to 90 degrees on an arm board. **B,C.** The forearm can then be supinated or pronated depending on the choice of a volar or dorsal approach, respectively.

- Cannulated headless compression screws, in which the differential thread pitch exerts compression across the fracture site¹

Positioning

- Anesthesia should be general or regional.
- The patient should be positioned supine, with the shoulder of the affected upper extremity abducted to 90 degrees on an arm board (**FIG 4**).
- The fluoroscopy unit should be draped and readily available.
- A pneumatic tourniquet should be applied to the proximal upper arm.
- Intravenous antibiotic prophylaxis should be provided prior to tourniquet inflation.
- The upper extremity should be prepped and draped in the standard sterile fashion.
- The upper extremity should then be exsanguinated using an Esmarch bandage, and then the tourniquet should be inflated (to either 250 mm Hg or at least 100

more than systolic blood pressure).

Approach

- Scaphoid fractures can be approached from a volar or dorsal approach.

TECHNIQUES

■ Open Reduction and Internal Fixation of Scaphoid Fracture: Dorsal Approach

Exposure

- Make a longitudinal 3- to 4-cm-long incision in the dorsal forearm and hand starting at the ulnar aspect of the Lister tubercle and extending distally (**TECH FIG 1A**).
- Dissect through subcutaneous tissue; elevate skin flaps on either side above level of extensor retinaculum. Identify and protect any crossing radial sensory nerve branches.
- Incise the distal aspect of the extensor retinaculum over the third compartment. Identify the junction of the second and third dorsal compartments.
- Identify and retract EDC ulnarly and ECRB, ECRL, and EPL radially to expose the underlying radiocarpal capsule. The tendons can remain in their compartment but must be identified to avoid inadvertent transection during exposure of the capsule.
- Make a limited capsulotomy to expose the scaphoid. The scaphoid can be approached through a transverse limb just distal to dorsal radius (**TECH FIG 1B**). An inverted T incision can be extended if further exposure is needed.
- Elevate the capsular flap to expose the proximal pole of the scaphoid, the S-L ligament, and the underlying fracture. Be careful to avoid stripping the dorsal ridge vessels entering at scaphoid waist.
- Evacuate fracture hematoma.

TECH FIG 1 • A. Longitudinal approximately 4-cm incision designed along the axis from the Lister tubercle to the long finger metacarpal. This incision is used for a dorsal approach to the scaphoid. **B.** Intraoperative photograph of the dorsal approach depicting scaphoid and intact scapholunate (SL) ligament. Note the position of the buried screw head as well. P, proximal; D, distal; U, ulnar; R, radial.

Fracture Reduction and Fixation

- Apply longitudinal traction on IF and LF to distract the carpus.
- If needed to assist in fracture reduction, insert 0.045-in. K-wires perpendicular into proximal and distal scaphoid fragments (**TECH FIG 2**).
- Reduce fracture; confirm by assessing congruity of radioscaphoid and scaphocapitate articulations.
- Once reduction is confirmed, temporarily fixate with derotational 0.045-in. K-wires. Drill first wire dorsoulnar to central axis of scaphoid, into the trapezium. Drill a second wire, if needed, volar and radial to central axis of scaphoid. Be careful to ensure that derotational wires will not interfere with screw placement and/or prevent compression within the central axis of the scaphoid (see **TECH FIG 2**).

TECH FIG 2 • Inserting 0.045-in. K-wires into proximal and distal fragments to act as “joysticks” may significantly assist in fracture reduction. Also note the placement of a derotational 0.045-in. K-wire for temporary fixation, once the fracture is appropriately reduced. Importantly, this wire should be placed parallel to but not within the central axis of the scaphoid, to avoid interfering with screw placement.

Guidewire Placement

- Guidewire placement should originate at the membranous portion of the origin of the scapholunate ligament. For very proximal fractures, the starting point should be the mid-aspect of the membranous portion of the scapholunate ligament, to be as proximal as possible.
- Flex the wrist, and insert the guidewire down the central axis of the scaphoid. This should be in line with the thumb metacarpal.

- Confirm central axis placement via PA, lateral, and 30-degree pronated lateral radiographs.
- Advance the wire up to the scaphotrapezial joint without entering the joint itself.

Screw Insertion

- Determine screw length via the guidewire. With minimal displacement of the fracture, screw length should be 4 mm shorter than guidewire length to account for the cartilage thickness.
- Advance the guidewire into the trapezium.
- Use the cannulated drill to manually drill over the wire. Be careful to not overdrill the distal scaphoid, which could result in screw migration into the scaphotrapezial joint.
- Remove the drill and insert the screw along the central axis of the scaphoid.
- Remove the guidewire.
- Confirm screw position via radiographs (**TECH FIG 3**).
- Close the radiocarpal capsule and then the extensor retinaculum if completely released, then skin.

TECH FIG 3 • Final confirmation of appropriate screw position via PA (**A**), lateral (**B**), and 30-degree pronated lateral (**C**) radiographs. Note the screw positioning lies within the scaphoid cortex on all views, reducing the chance of undesired prominence.

■ Open Reduction and Internal Fixation of Scaphoid Fractures: Volar Approach

Exposure

- Palpate the tubercle of the scaphoid after radially deviating the wrist.
- Design a 3- to 4-cm incision centered over the palpated tubercle, extending proximally over the FCR tendon sheath and distally over the base of the thumb.
- Incise the FCR sheath and retract the tendon ulnarly, exposing underlying volar wrist capsule.
- Distally, divide thenar muscles over the distal scaphoid and trapezium.
- Incise the volar wrist capsule longitudinally, avoiding injury to the articular cartilage.
- Divide the radiolunate and radioscapnocapitate ligaments in the proximal field to visualize the proximal pole of the scaphoid.
- Use a Freer elevator to expose the scaphotrapezial joint. Limit dissection over the radial scaphoid to avoid injury to dorsal vessels.
- Evacuate fracture hematoma and irrigate.

Fracture Reduction and Fixation

- Apply longitudinal traction to the wrist and reduce the fracture. Consider using pointed reduction forceps or placing 0.045-in. K-wires into proximal and distal scaphoid fragments to assist in reduction.
- Place provisional 0.045-in. K-wire, starting from volar distal to dorsal proximal, for temporary fixation. Ensure the trajectory is not along the central axis of the scaphoid.
- To expose starting position for screw placement dorsally, resect small portion of proximal volar trapezium.
- Place central axis guidewire.
- Determine screw length via the guidewire. With minimal displacement of the fracture, screw length should be 4 mm shorter than guidewire length to account for the cartilage thickness.
- Advance the guidewire into the radius.
- Use the cannulated drill to manually drill over the wire.
- Insert the cannulated screw along the central axis; confirm via PA, lateral, and 30-degree pronated lateral radiographs.

- Repair radiolunate and radioscapohcapitate ligaments.
- Close the volar wrist capsule, then skin.

PEARLS AND PITFALLS

Preservation of scaphoid blood supply

- Avoid dissection on the dorsal ridge of the scaphoid.
- Limit dissection of capsule.

Guidewire positioning

- During dorsal approach, pronate and flex the wrist to ensure appropriate trajectory.
- During volar approach, resect small volar lip of trapezium to expose starting position in distal pole of scaphoid.
- Ensure the guidewire is placed along the central axis.

Screw position

- Assess screw length and prominence intraoperatively via 45-degree supination oblique and pronated oblique radiographs.
- Screw length should be 4 mm shorter than measured length.
- Stop drilling 2 mm short of the distal pole when using the dorsal approach.
- Place the screw in the central axis.
- Bury the headless compression screw beneath the cortical surface of the scaphoid to prevent screw prominence and cartilage erosion.

Small proximal pole fracture

- Consider a smaller screw such as Acutrak Mini to prevent proximal fragment comminution.

Unstable fracture reduction

- Place perpendicular joystick K-wires into proximal and distal fragments to aid in reduction.
- Stabilize fragments prior to screw insertion via derotational K-wires.

POSTOPERATIVE CARE

- Patients should be placed in a volar thumb spica splint.
- Patients should strictly elevate at home to reduce edema and pain.
- Frequent ROM exercises of the digits are crucial to prevent unwanted stiffness.

- At 2 weeks postoperatively, patients should return for suture removal and exchange to a removable forearm-based thumb spica splint. ROM exercises of the thumb are started at this point.
- Fractures that involve the proximal pole, or fractures with significant comminution, should be immobilized for 6 to 10 weeks.
- Radiographs should be taken at the 2-, 6-, and 12-week postoperative time points to assess for fracture healing (**FIG 5**).
- CT scans can be considered to better assess for fracture union at 12 weeks or later if there are concerns about healing.

OUTCOMES

- Outcomes depend on type of treatment, timing of treatment, and location of screw placement.
- A recent systematic review concluded that internal fixation reduces the risk of nonunion compared with cast immobilization (1.7% vs 10%, respectively). However, the two treatments did not differ in terms of eventual postoperative pain, tenderness, long-term grip strength, ROM, functional outcome, and satisfaction, although internal fixation may produce quicker return to function and transiently improved ROM and grip strength.⁹
- Rigid internal fixation theoretically allows for earlier physical therapy, lesser time to union, improved ROM, and quicker functional recovery. This has been corroborated by studies that have showed high rates of union and good overall outcomes using open techniques¹⁰ (**FIG 6**).
- Time to initiation of treatment highly influences union rates:
 - Scaphoid fractures treated before 4 weeks have a significantly higher union rate than do those treated after 4 weeks.¹¹
 - Nondisplaced fractures casted within 3 weeks of injury have a 90% to 100% union rate,¹² whereas those casted between 6 weeks and 6 months from injury demonstrate a 90% union rate, but approximately twice as long duration to achieve a union.¹³
- Central screw placement exhibits more rapid progression to union, in cases of scaphoid nonunion.¹⁴

FIG 5 • A: PA and **(B)** lateral PA and lateral radiographs showing reduced, internally fixed, and united scaphoid waist fracture at roughly 3 months postoperatively.

FIG 6 • Early outcome (at 12 weeks postoperatively) depicting intact grip and wrist flexion/extension.

COMPLICATIONS

- Screw prominence, erosion of the scaphotrapezial articulation, and erosion of the distal radius articular surface are possible if the screw length is not accurately estimated intraoperatively.
- Displaced waist and proximal pole fractures can lead to nonunion and potential AVN.
- Rare but potential other complications include wound infections, hypertrophic scarring, injury to sensory branch of radial nerve, and damage to scaphotrapezial articulation.

Scaphoid Nonunion: Nonvascularized Bone Reconstruction

18

CHAPTER

Matthew L. Iorio and Jason H. Ko

DEFINITION

- Scaphoid nonunion is defined as failure to heal within 6 months. The incidence of scaphoid nonunion is between 4% and 50%.
 - Nonunion may be evidenced by pain and tenderness at the anatomic snuffbox and scaphoid tubercle, and decreased wrist extension.
- Radiographs demonstrate a wide, sclerotic fracture cleft, potentially with cyst formation (**FIG 1**).
- Unstable nonunions demonstrate loss of the normal length and shape of the scaphoid, often with a dorsal intercalated segmental instability (DISI) deformity.
- When not corrected, carpal instability ensues, and a predictable pattern of degenerative changes known as scaphoid nonunion advanced collapse (SNAC) arthritis occurs.
- The preferred treatment for scaphoid nonunions is internal fixation with autologous bone grafting.
- Nonvascularized bone grafts have been the traditional treatment for scaphoid nonunion, although avascular necrosis (AVN) of the proximal pole is an indication for the use of vascularized bone grafts.

ANATOMY

- Seventy to 80% of the intraosseous vascularity comes from the dorsal scaphoid branches of the radial artery, entering through the dorsal ridge. These dorsal vessels enter the scaphoid waist in a retrograde direction, providing the single dominant intraosseous vessel to the proximal pole of the scaphoid.

- A minor volar contribution comes from radial artery or its superficial palmar branch, which gives off several volar scaphoid branches at the level of the radioscaphoid joint, entering the bone at its distal tubercle.

FIG 1 • Scaphoid waist nonunion characterized by a wide sclerotic fracture cleft with no evidence of bony healing.

- Because of this unique vascular anatomy, the proximal pole of a fractured scaphoid is particularly prone to AVN, especially when the fragment is small.
- A nonunion through the scaphoid waist can lead to progressive flexion of the distal pole and extension of the proximal pole, leading to a “humpback deformity.”
- Treatment and surgical approach will be influenced by whether or not a humpback deformity or DISI deformity is present.
- A proximal pole nonunion will not typically develop a humpback deformity; however, the risk of AVN is higher.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Injury typically involves axial load across a hyperextended and radially deviated wrist.
- Tenderness can typically be found over the distal pole of the scaphoid volarly or along the proximal pole dorsally within the interval between the first and

third extensor compartments.

- Ulnar-to-radial wrist deviation with pressure over the volar scaphoid pole may cause increased pain, as will active assist wrist flexion or extension or resisted pronation.

IMAGING

- Anteroposterior, oblique, and lateral radiographs of the scaphoid should be obtained.
 - Standard scaphoid view involves 30 degrees of wrist extension and 20 degrees of ulnar deviation.
 - Stress views with the fist tightly clenched may demonstrate dynamic instability of the scaphoid or nonunion site.
- Computed tomography (CT) with fine cuts may be beneficial in further characterizing the nonunion site, as well as associated humpback deformity, cyst formation, osteophytosis, and degenerative arthrosis.
 - Increased proximal pole sclerosis or density on imaging may indicate AVN, which, depending on the location of the nonunion, may limit both the ability to obtain viable bone margins as well as reliable fixation and osseous union.
- Magnetic resonance imaging can be used to assess for AVN of the scaphoid proximal pole.
- Evaluation of a potential degenerative posture or malunions of the scaphoid should be measured and documented as part of the initial evaluation. There is some debate as to which is superior in interobserver reliability, though they both function to evaluate deviations of scaphoid posture from a normative comparison in the setting of humpback deformity and collapse.
 - A lateral intrascaphoid angle is obtained by drawing a line perpendicular to the proximal and distal articular surfaces.
 - A normal lateral intrascaphoid angle is 24 ± 5 degrees or less than 3 degrees.¹
 - Increasing flexion results in a humpback deformity, with a lateral intrascaphoid angle greater than 35 degrees.
 - The scaphoid height-to length ratio is evaluated on a lateral or sagittal image. A normal ratio is 0.60 ± 0.04 .
 - For scaphoid length, a baseline is drawn along the volar scaphoid, and the length of the scaphoid is found from the most proximal to the most distal aspect.

- For scaphoid height, the maximum height of the scaphoid was found on a line perpendicular to the baseline.

SURGICAL MANAGEMENT

- Nonvascularized bone graft reconstruction should be considered for the treatment of all scaphoid fracture nonunions that demonstrate no incidence of AVN of the proximal pole.
- Contraindications
 - Progressive pan-carpal arthrosis can follow prolonged scaphoid nonunions in a predictable pattern: SNAC wrist deformity.
 - The presence of radiocarpal or midcarpal sclerosis, with cyst formation, may indicate advanced disease with continued postoperative pain. In this instance, salvage procedures including proximal row carpectomy, limited intercarpal arthrodesis, or total wrist arthrodesis may be more reliable in regard to pain control.
 - Relative contraindications include the patient's suitability for surgery, smoking status, and understanding of the need for prolonged postoperative immobilization and use restrictions.

Positioning

- The patient is positioned supine on the operating room table with a well-padded tourniquet placed on the upper arm.
- General anesthesia or monitored anesthesia care (MAC) can be used, but supplementation with an infraclavicular or interscalene nerve block may markedly improve postoperative pain control.

Approach

- If a humpback deformity is present, a volar approach is used, which provides excellent exposure to the waist and distal pole of the scaphoid.
 - It also provides direct access to the extension osteotomy wedge for direct bone grafting and stabilization.
 - It may be possible that this exposure, by preserving the dorsal ridge vessel, may prevent iatrogenic devascularization of the scaphoid.
- If there is no humpback deformity, a dorsal or volar approach can be used, based on the location of the nonunion. Dorsal approaches are preferred for more proximal nonunions, and volar approaches are preferred for more distal nonunions.

- Either a volar or dorsal approach can be used with a waist nonunion without a humpback deformity.

TECHNIQUES

■ Scaphoid Bone Grafting: Volar Approach

Exposure and Preparation of the Site

- Under tourniquet control and loupe magnification, a longitudinal incision is made in-line with the flexor carpi radialis (FCR) to the level of the proximal wrist crease, followed by a 60-degree angle at the volar junction of the glabrous skin. This will protect the radial artery and prevent a longitudinal scar across the flexor crease. This is also referred to as the Russe approach (**TECH FIG 1A–C**).
- The deep branch of the radial artery is visualized, and retracted radially.
- An intrasubstance longitudinal incision in the radioscaphocapitate (RSC) ligament can be created for exposure of the volar scaphoid. The incision and exposure should be at least distal to the scaphotrapezium joint, for preparation and visualization of screw placement.
- Following visualization of the scaphoid, 0.045-in. (or larger) K-wires may be placed proximal and distal to the fracture as “joysticks” to retract and see, and correct any humpback deformity that may be present (**TECH FIG 1D**).
- In the event of a malunion, an osteotomy can be performed; however, this should be done judiciously. We recommend only crossing 80% to 90% of the scaphoid waist with the osteotome to prevent penetration of the dorsal cortex and injury to the scaphocapitate joint or the dorsal ridge vessel.
- Disruption of the dorsal scaphoid can create an unstable fracture or make cancellous bone graft placement less secure.
- Following exposure, the nonunion site must be cleared of intervening fibrous material and necrotic bone, but viable cancellous bone should remain. A small dental pick or curette can be useful in this setting.

Obtaining Bone Graft

- If volar distal radius autograft is to be used, the pronator quadratus is incised and dissected subperiosteally to expose the volar cortex of the distal radius

(TECH FIG 2A).

- The site of bone graft harvest should be confirmed with intraoperative fluoroscopy, being careful not to harvest graft too close to the radiocarpal joint.
- A structural corticocancellous bone graft can be obtained either with straight and curved osteotomes or with an oscillating saw.
 - If a saw is used, saline irrigation should be applied during the osteotomies to minimize thermal injury to the bone (**TECH FIG 2B,C**).
- Through the aforementioned cortical window, cancellous autograft can be harvested.
- For most scaphoid nonunions without AVN, distal radius autograft is sufficient.
 - However, iliac crest autograft is the traditional standard for scaphoid nonunion treatment. The anterosuperior iliac spine (ASIS) is palpated, and bone graft should be harvested 2 cm posterior to the ASIS.

TECH FIG 1 • A–C. A volar Russe incision along the FCR tendon with an oblique extension over the scaphoid distal pole provides access to the volar scaphoid. **D.** Through this volar approach, 0.054-in. Kirschner wires used to joystick open the scaphoid fracture nonunion site, correcting the humpback

deformity.

- The skin incision is made posterior to the ASIS, and dissection should proceed with monopolar cautery directly down to the iliac crest.
- Bicortical grafts from the inner table or outer table, or tricortical grafts, can be obtained, typically with an oscillating saw.

Stabilizing the Site

- The nonunion site can then be stabilized by either progressively packing either corticocancellous or cancellous graft into the site, effectively expanding the space and increasing the extension of the distal pole.
- K-wire joysticks can be used to provide an extension force through the fracture, and a longitudinal K-wire can be placed to provide a mechanical restraint to flexion.
 - In our experience, a combination of the two may work best, where the extension is corrected with the K-wires and stabilized longitudinally as best as possible and confirmed with fluoroscopy.
- This wire should be placed slightly off axis to avoid the ultimate trajectory of compression screw placement and directly capture the bone graft.
 - Alternatively, the wire can be placed slightly volar to the bone graft to prevent extrusion during compression.
- If a large cortical defect volarly is present in the extension wedge, a bone graft can be tailored to slightly overfill the space.
 - The longitudinal wire is then backed out just proximal to the fracture, the graft is press fit into the space, and the wire is readvanced (**TECH FIG 3**).

Scaphoid Fixation

- Osteosynthesis is then completed, most frequently with either K-wire or compression screw placement.

TECH FIG 2 • A. The pronator quadratus has been elevated subperiosteally off the volar surface of the distal radius. The purple markings are used to plan the osteotomies, which were confirmed with intraoperative fluoroscopy. **B,C.** A corticocancellous autograft is harvested from the volar distal radius. This type of graft can be used as a structural graft to correct a humpback deformity.

TECH FIG 3 • Corticocancellous autograft is press-fit into the scaphoid nonunion through a volar approach.

- For compression screw placement from the volar scaphoid, the guidewire can be advanced through either the trapeziometacarpal joint or scaphotrapezial joint, with similar outcomes.
- In the scaphotrapezial approach, however, the volar beak or footplate of the trapezium should be first removed with a rongeur to prevent off-axis screw placement.
- The stabilizing K-wire should be left in place or repositioned if it is blocking the guidewire, to provide rotational control during drilling and compression.

- Following placement of the guidewire, the drill should be advanced with the aid of fluoroscopy to prevent penetration of the far cortex, as this may destabilize the distal screw and lead to screw loosening.
- Screw selection then is performed by drilling to the distal subchondral bone, measuring based off the guidewire, and selecting a screw length 4 to 6 mm shorter than the measured length to ensure that the screw is adequately buried in subchondral bone proximally, without distal extrusion.
- Depending upon the manufacturer, there may be several screw widths to choose from, typically between 2 and 3 mm. This becomes relevant in either revising a prior attempt to heal an acute fracture with a compression screw or expectations in need for nonunion revision. That is, if the widest screw is chosen as the initial fixation and it fails, compression screw fixation may not be an option for salvage given the subsequent bone loss and instability. Therefore, initial fixation should be performed with a narrower screw, in case future revision with a wider screw can be performed (**TECH FIG 4**).

TECH FIG 4 • AP and lateral intraoperative fluoroscopic views of a headless compression screw to provide compression across the corticocancellous bone graft reconstruction. The radial K-wire in the AP view is used as a derotational pin, and the volar K-wire on the lateral view is used to further stabilize the small bone graft.

■ Scaphoid Bone Grafting: Dorsal Approach

Exposure and Preparation of the Site

- Under tourniquet control and loupe magnification, a longitudinal incision is made just ulnar to the Lister tubercle (**TECH FIG 5A**).
- A longitudinal cut or step-cut is made through the extensor retinaculum.
- The third dorsal compartment is released, and the EPL tendon is retracted radially.
- Subperiosteal dissection of the second and fourth dorsal compartments is performed to expose the dorsal distal radius.
- The posterior interosseous nerve (PIN) is located in the floor of the fourth compartment, and during the dorsal wrist approach, a PIN neurectomy can be performed to help minimize postoperative pain.
- A ligament-sparing capsulotomy or longitudinal capsulotomy is performed through the dorsal wrist capsule to expose the proximal scaphoid (**TECH FIG 5**).

TECH FIG 5 • A. A dorsal longitudinal incision just ulnar to the Lister tubercle will give the surgeon access to both the scaphoid nonunion and the dorsal distal radius bone graft site. **B.** A ligament-sparing

capsulotomy is performed parallel to the dorsal intercarpal (DIC) and dorsal radiocarpal (DRC) ligaments, along with a radial extension.

- The nonunion site is exposed and fibrous tissue removed until healthy-appearing cancellous bone is visualized both proximally and distally.
- Care is taken not to disrupt the scapholunate interosseous ligament during the procedure.

Scaphoid Fixation

- As described above, K-wires can be used as joysticks to gain control of the proximal and distal poles, and corticocancellous or cancellous autograft can be packed into the nonunion site.
- Fixation is achieved by headless compression screw, as described above. The derotational K-wire can be left in for temporary fixation.
- In proximal pole nonunions, if there is minimal bone proximally, screw fixation may not be possible, in which case, definitive fixation may be performed with K-wires.
- Allograft bone chips can be used to pack the bone graft donor site.
- With the volar approach, it is important to reapproximate the radioscaphocapitate ligament if it was cut during the procedure. This can be performed with 3-0 polyglactin suture.
- If volar distal radius bone graft was harvested, the pronator quadratus does not need to be repaired.

Closure

- The dorsal capsule is carefully closed with an absorbable suture, such as a 3-0 poliglecaprone-25 or polyglactin suture. The extensor retinaculum is closed with similar 3-0 suture, leaving the extensor pollicis longus tendon superficial to the retinaculum.
 - Depending upon the volume of expected postoperative edema and skin quality, the skin is closed with either deep dermal stitches and a running subcuticular or horizontal mattress stitches with 4-0 nylon.
 - The wrist is immobilized in a well-padded plaster short-arm spica splint.
-
-

PEARLS AND PITFALLS

Scaphoid preparation

- Degeneration of the radioscaphoid facet or post-traumatic arthrosis may predispose to ongoing pain and stiffness and should be considered a potential contraindication to scaphoid salvage techniques.

Distal radius bone graft harvest

- It is important to harvest bone graft 1 cm proximal to the radiocarpal joint to prevent injury.

PIN neurectomy

- During the dorsal wrist approach, the PIN can be identified in the floor of the fourth dorsal compartment and excised to help minimize postoperative pain.

FIG 2 • CT scans obtained 6 weeks postoperatively after volar distal radius corticocancellous reconstruction of a scaphoid waist nonunion demonstrate healing across the proximal and distal autograft sites.

POSTOPERATIVE CARE

- The patient is placed in a well-padded thumb spica splint. At 2 weeks, the splint and stitches are removed and a thumb spica cast is applied.
- Casting is typically continued for a total of 10 to 12 weeks, with cast changes

at 3- to 4-week intervals.

- X-rays should be obtained at each postoperative visit. CT scans can be obtained at the surgeon's discretion any time after 6 weeks postoperatively to determine extent of union (**FIG 2**).
- Exposed K-wires should be removed near 3 to 4 weeks to prevent pin site infections and possible bacterial colonization of the nonunion site. Buried wires can be removed in the office or operating room once union is verified.
- Osseous union is identified by bridging trabeculae on radiographs and absence of fracture site tenderness (**FIG 3**).

OUTCOMES

- In 1936, Matti described the original technique using an iliac crest corticocancellous bone strut as an inlay through a dorsal approach. Russe later offered a modified technique done via a volar approach to spare the blood supply and correct volar collapse. This technique demonstrated union rates ranging from 81% to 97%.²
- The Fisk-Fernandez technique employs a triangular or trapezoidal corticocancellous wedge from the iliac crest or distal radius that is placed as an intercalary structural graft to restore scaphoid length and correct carpal alignment. Such wedge-grafting techniques have demonstrated improved union rates when compared to Matti-Russe inlay grafting technique.³⁻⁶

FIG 3 • Routine x-rays at 10 months postoperatively demonstrate complete healing of the scaphoid

nonunion reconstruction, with pain-free range of motion.

- Sayegh and Strauch performed a systematic review comparing cancellous-only and corticocancellous grafts, reporting cancellous-only grafts provided a shorter interval to union, but corticocancellous grafts were associated with consistent deformity correction and improved Mayo wrist scores.⁷

COMPLICATIONS

- The most common complication is superficial wound or pin site infection, nerve irritation, and complex regional pain syndrome (1.25%).^{8,9}

Scaphoid Fracture

Nonunion: Vascularized Bone Reconstruction

19

CHAPTER

Matthew L. Iorio and Jason H. Ko

DEFINITION

- Scaphoid fractures are among the most common upper extremity fractures, accounting for 70% of all carpal bone fractures.¹
- Although most scaphoid fractures heal with nonoperative management, the tenuous blood supply of the scaphoid can lead to nonunion in 5% to 10% of cases even with appropriate treatment, and up to 55% of cases when there is displacement on initial injury (**FIG 1**).^{2,3}
- The complications of scaphoid nonunion vary widely, from pain and decrease in function to carpal malalignment, progressive arthrosis, and eventual scaphoid nonunion advanced collapse (SNAC) (**FIG 2**).^{3,4}
- To prevent such complications, surgical advances have been developed to treat scaphoid nonunions, including screw fixation, bone grafting, and, most recently, vascularized bone grafting.⁵
- Vascularized bone grafts (VBGs) have been shown to promote healing and realignment of recalcitrant scaphoid nonunions in addition to re-establishing blood flow in cases with avascular necrosis (AVN).⁶

FIG 1 • Chronic scaphoid waist nonunion with tapered cortical edges.

FIG 2 • Radiocarpal joint with avascular proximal scaphoid pole and cartilage fragmentation (Freer elevator).

ANATOMY

- Seventy to 80% of the intraosseous vascularity comes from the dorsal scaphoid branches of the radial artery, entering through the dorsal ridge. These dorsal vessels enter the scaphoid waist in a retrograde direction, providing the single dominant intraosseous vessel to the proximal pole of the scaphoid.
- A minor volar contribution comes from the radial artery or its superficial palmar branch, which gives off several volar scaphoid branches at the level of the radioscapoid joint, entering the bone at its distal tubercle.
- Because of this unique vascular anatomy, the proximal pole of a fractured scaphoid is particularly prone to AVN, especially when the fragment is small.
- Progressive collapse and flexion through the nonunion cause dorsal rotation of the lunate or subluxation of the midcarpal joint leading to a DISI deformity (dorsal intercalated segment instability).

PATIENT HISTORY

- Injury typically involves axial load across a hyperextended and radially deviated wrist.
- Tenderness can typically be found over the volar pole of the scaphoid or along

the dorsal pole within the interval between the first and third extensor compartments.

- Ulnar-to-radial wrist deviation with pressure over the volar scaphoid pole may cause increased pain, as will active assist wrist flexion or extension or resisted pronation.

IMAGING

- Anteroposterior, oblique, and lateral radiographs of the scaphoid should be obtained.
- Standard scaphoid view involves 30 degrees of wrist extension and 20 degrees of ulnar deviation.
- Stress views with the fist tightly clenched may demonstrate dynamic instability of the scaphoid or nonunion site.
- Computed tomography (CT) with fine cuts may be beneficial in further characterizing the nonunion site, as well as associated collapse, cyst formation, osteophytosis, and degenerative arthrosis.
 - Increased proximal pole sclerosis or density on imaging may indicate AVN, which, depending on the location of the nonunion, may limit both the ability obtain viable bone margins as well as reliable fixation and osseous union.
- Magnetic resonance imaging can be used to assess for AVN of the scaphoid proximal pole.
- Evaluation of a potential degenerative posture or malunions of the scaphoid should be measured and documented as part of the initial evaluation. There is some debate as to which is superior in interobserver reliability, though they both function to evaluation deviations of scaphoid posture from a normative comparison in the setting of humpback deformity and collapse.
- A lateral intrascaphoid angle is obtained by drawing a line perpendicular to the proximal and distal articular surfaces.
 - A normal lateral intrascaphoid angle is 24 ± 5 degrees, or less than 3 degrees.
 - Increasing flexion results in a humpback deformity, with a lateral intrascaphoid angle greater than 35 degrees.
- The scaphoid height-to-length ratio is evaluated on a lateral or sagittal image. A normal ratio is 0.60 ± 0.04 .
 - For scaphoid length, a baseline is drawn along the volar scaphoid, and the length of the scaphoid is found from the most proximal to the most distal aspect.

- For scaphoid height, the maximum height of the scaphoid was found on a line perpendicular to the baseline.

SURGICAL MANAGEMENT

- Harvest of the osteocutaneous medial femoral condyle (MFC) microvascular flap provides simultaneous soft tissue and bone for reconstruction, ease of soft tissue recipient closure, and the ability to provide accurate postoperative monitoring of the microcirculation of the flap. Its routine use requires an understanding of the arterial variation of the descending geniculate arterial tree, as well as the blood supply to the overlying skin of the medial aspect of the knee.
- The free MFC corticoperiosteal flap has garnered increasing attention due to its many desirable attributes, including ease of dissection, surgical positioning facilitating a two-team approach, low donor-site morbidity, preservation of all major arteries to the distal extremity, variable size and shape for harvest and in-setting, and osteogenic potential.⁷

Contraindications

- Progressive pan-carpal arthrosis can follow prolonged scaphoid nonunions in a predictable pattern: SNAC wrist deformity.
- The presence of radiocarpal or midcarpal sclerosis, with cyst formation, may indicate advanced disease with continued postoperative pain. In this instance, salvage procedures, including proximal row carpectomy, limited intercarpal arthrodesis, or total wrist arthrodesis, may be more reliable for pain control.
- Relative contraindications include the patient's suitability for surgery, smoking status, and understanding of the need for prolonged postoperative immobilization and use restrictions.

Positioning

- The patient is placed supine on the operating room table, and a well-padded tourniquet is placed on the upper arm.
- General anesthesia or monitored anesthesia care (MAC) can be used, but supplementation with an infraclavicular or interscalene nerve block may markedly improve postoperative pain control.

TECHNIQUES

■ Approach to Creation of the Bone Flap

- When there is no humpback deformity, a dorsally based vascularized bone flap from the distal radius, like the 4 + 5 extensor compartmental artery (ECA) flap or the 1,2-intercompartmental supraretinacular artery (1,2-ICSRA) flap, can be used to reconstruct a scaphoid nonunion.
- When a humpback deformity is present in the setting of AVN, however, a structural flap must be placed volarly, so a volar vascularized bone flap or a free MFC (or MFT) flap is required to properly correct the humpback deformity.

4 + 5 Extensor Compartmental Artery Vascularized Bone Flap

- The 4 + 5 ECA pedicle is based on retrograde flow between the anterior interosseous pedicle and the dorsal extensor compartmental arteries (**TECH FIG 1A,B**).
- Under tourniquet control, a standard dorsal approach to the wrist is used for exposure, incorporating prior incisions when appropriate.
- The dorsal radial sensory branches are identified and swept radially to protect them from iatrogenic injury.
- The third extensor compartment is opened and the tendon transposed.
- Retinacular flaps are elevated from the ulnar border of the Lister tubercle, moving radially and incorporating the retinaculum over the second dorsal compartment.
- Just distal to the radiocarpal joint and retinaculum, the fourth extensor compartment and tendons are mobilized from the dorsal capsule, preventing iatrogenic injury to the vascular pedicle.
- The tendons are then retracted ulnarly, exposing the anterior interosseous artery and neurovascular pedicle proximally and its distal anastomotic connections to the fourth and fifth extensor compartmental arteries.

TECH FIG 1 • **A.** Illustration demonstrating the fourth and fifth extensor compartmental artery (4 + 5 ECA) flap and its axis of rotation. **B.** Fourth extensor compartment artery (*arrow*). **C.** Capsular vascularized bone graft distally based on the fourth extensor compartment artery. **D.** Placement of the distally based fourth ECA flap in the proximal pole of the

scaphoid for avascular necrosis.

- Osteotomies are then designed with the vascular pedicle longitudinally centered and the distal transverse cut at least 1 cm proximal to the dorsal ridge of the radius.
- Distal to the site of osteotomy, the pedicle should be elevated with a sharp periosteal elevator or Freer.
- The proximal vessel is clipped, and the osteotomies are performed, taking great care to prevent disruption of the volar radial cortex.
- The flap is then reflected, with a wide cuff of capsular tissue around the retrograde ECA (**TECH FIG 1C,D**).
- The tourniquet can be released at this point to verify perfusion of the bone flap.

1,2-Intercompartmental Supraretinacular Artery Vascularized Bone Flap

- The 1,2-intercompartmental supraretinacular artery (1,2-ICSRA) is distally based from the dorsal continuation of the radial artery into the radiocarpal arch (**TECH FIG 2A**).
- Gentle exsanguination prior to tourniquet elevation can provide some continued turgor of the vascular pedicle, which can improve visibility and dissection.
- Prior dorsal longitudinal incisions can be incorporated when possible into a curvilinear dorsoradial longitudinal incision that follows the course of the EPL tendon (**TECH FIG 2B**).
- The dorsal radial sensory nerve should be identified in the interval next to the cephalic vein and carefully protected.
- Deep to this, the 1,2-ICSRA can be identified on the septum between the first and second extensor compartments, which are incised laterally to include a broad cuff of tissue including the accompanying venae comitantes (**TECH FIG 2C,D**).
- The vertical perforating nutrient branches of the pedicle enter the periosteum at an average of 15 mm proximal to the dorsal radiocarpal joint line.

TECH FIG 2 • A. The 1,2-ICSRA bone flap with curvilinear incision following the course of the EPL tendon. **B.** The incision follows the course of the EPL tendon. **C.** 1,2-ICSRA vascular pedicle highlighted by the Ragnell retractor. **D.** The 1,2-ICSRA vascularized bone flap harvested.

- If desired, a dorsal radiocarpal capsulotomy can be performed to visualize the scaphoid nonunion.
- The proximal vessel is ligated with bipolar diathermy, and the flap is osteotomized with the vascular pedicle longitudinally centered.
- Prior to performing the distal osteotomy, a periosteal elevator should be used to elevate the periosteal sleeve and protect the distally based pedicle.

Superficial Palmar Branch of Radial Artery Vascularized Bone Flap

- The superficial palmar branch of the radial artery is a terminal transverse branch of the radial artery that arborizes on the distal cortex of the radius. The branch can be identified and preserved in the standard volar approach to the scaphoid, which may be useful especially in settings of humpback or flexion deformities that are typically approached from the volar wrist (**TECH**

FIG 3).

- Following exsanguination and tourniquet control, a longitudinal incision in line with the flexor carpi radialis (FCR), with a lateral extension (approximately 45 degrees) at the wrist crease along the glabrous skin junction can be used for exposure.
- The superficial palmar branch is then identified in line with the FCR tendon, potentially originating 5 to 8 mm proximal to the radial styloid. It may be useful to identify the proximal radial artery and trace it distally to the takeoff of the palmar vessel, thereby preventing inadvertent injury to the pedicle.
- The posterior sheath of the FCR tendon is then opened, and the volar wrist capsule is identified.
- A longitudinal incision in the radioscaphocapitate (RSC) ligament exposes the scaphoid and facilitates direct tendon repair at the time of closure.
- Following scaphoid preparation, the pronator quadratus is incised longitudinally and transversely to exposure the volar distal radius cortex.
- Care should be taken to harvest the graft at least 10 mm proximal to the volar rim to prevent disruption of the radioscaphoid facet.

Medial Femoral Condyle Microvascular Flap

- Flap dissection can be approached with or without the intent of harvesting a skin paddle, regardless of the variations in anatomy.

TECH FIG 3 • Volar vascularized bone flap based on the volar carpal artery.

- A Doppler signal can be routinely located over the apex of the medial condyle of the femur.
- A sweeping, curvilinear incision is created, starting at the Hunter canal and moving in distal and anterior directions to the midpoint between the medial border of the patella and the MFC, just anterior to the location of the Doppler signal (**TECH FIG 4A**).
- The incision then continues distal and posterior, stopping 2 to 3 cm below the joint line and just posterior to the midaxis of the leg.
- This skin incision is continued to the subfascial plane of the vastus medialis muscle, which allows the skin paddle to be rapidly elevated and retracted in a posterior direction as the vastus medialis is dissected in an anterior direction.
- The DGA can then be identified as the medial column of the femur is exposed. Dissecting subfascially ensures protection of all skin vessels that can branch off the distal DGA into the reflected skin.

- Through the fascial plane of the vastus medialis, the branching vessels emitting from the DGA can be identified, and the presence or absence of an SAB and/or DGA-CB is rapidly noted (**TECH FIG 4B,C**).
- Branches to the vastus medialis course in an anterior direction (penetrating the fascial plane) and are ligated.
- At this point, a decision is made regarding the approach for the skin paddle. This skin vessel is preferable because of the speed with which it can be dissected as well as the assurance that the skin and subcutaneous vasculature can be elevated anterior to the sartorius muscle and adductor tendon, keeping the skin and bone segments in the same dissection interval (between the vastus medialis and sartorius muscles).
- If the SAB is selected as the means of supplying the skin segment, it requires a careful distal dissection to determine whether it is supported by skin branches that pass anterior to the sartorius muscle (45%) and in the same surgical interval as the bone component or posterior to the sartorius muscle (55%). If it does pass posterior, it will require a distal elevation of the skin segment and careful passage deep to the sartorius muscle to reunite it with the bone segment before completing the flap harvest.
- After determining the presence or absence of the DGA-CB and the SAB, we prioritize the DGA-CB because of its speed of dissection and ease of visualization.
- If the skin segment is quite large, or if initial dissection reveals that the SAB contributes to the skin perfusion while passing anteriorly to the sartorius muscle, both sources of skin perfusion (SAB and DGA-CB) can be harvested en bloc. Otherwise, the SAB is clamped, and the tourniquet is released. The Doppler signal over the apex of the MFC is again obtained.
- The initial sweeping incision allows many variations of oblique or longitudinally oriented ellipses to be designed, using the initial incision as the anterior border of the skin component, while capturing the Doppler signal for the benefit of postoperative monitoring.
 - Care is taken to harvest this in such a manner that primary closure is simply achieved.

TECH FIG 4 • A. Markings for the medial femoral condyle and trochlea flaps. X marks the Doppler signal routinely located over the apex of the medial condyle of the femur. If a skin paddle is required, a sweeping, curvilinear incision is created at the midpoint between the medial border of the patella and the MFC. If no skin paddle is required, a longitudinal line just posterior to the medial femoral condyle can be used. **B.** In situ relationship of the medial femoral condyle bone flap and skin paddle based on the descending geniculate artery cutaneous branch (overlying sartorius tendon at the tip of the forceps). **C.** Free medial femoral trochlea flap based on the descending geniculate artery. Note the proximal origin of the saphenous artery branch, in this case from the descending geniculate artery, to provide irrigation for a skin paddle. **D.** Medial femoral condyle bone flap and skin paddle following osteotomy and elevation.

- The elevation of the posterior margin of the skin requires making note of the immediate proximity of the DGA-CB to the anterior surface of the adductor tendon.
 - This posterior incision should be carried down to the region posterior to the adductor tendon, giving wide berth to the DGA-CB.
 - When deep and posterior to the adductor tendon, the scalpel is then used to approach the posterior aspect of the tendon and cautiously elevate the DGA-CB off the adductor tendon while maintaining the adductor tendon integrity and preserving the critical DGA-CB.
 - This will enable the entire DGA and its periosteal branches to be preserved undisturbed on the surface of the cortical bone.
 - The bone segment is dissected in the width, length, and depth required, and the flap is then harvested on the common DGA origin vessel (**TECH FIG 4D**).
-

■ Scaphoid Preparation and Fixation

- If cyst formation or bone loss is present without a humpback deformity, a longitudinal 1.1-mm K-wire can be placed radial to the longitudinal axis of the bone to preserve the alignment of the proximal and distal poles.
 - The wire should be placed through the proximal dorsal pole radial and volar to the longitudinal axis of the bone to avoid interference with the placement of a subsequent compression screw or visualization of the fracture.
 - The wire can be advanced antegrade and captured through the volar hand, bringing the proximal edge flush to cartilage cap to prevent injury to the scaphoid facet during manipulation.
 - The proximal and distal poles can then be distracted on the wire to facilitate visualization.
- Fluoroscopy is used to verify the nonunion site.
 - A no. 15 or beaver blade scalpel can be used to gently open the fracture site. Small curettes should be used to remove any intervening cystic or fibrous material (**TECH FIG 5A**).
 - If desired, a 0.8-mm K-wire can be used to sparingly trephine the proximal and distal cancellous surfaces within the fracture, thereby increasing subsequent blood flow to the fracture site.

- The bone flap and nonunion site should be contoured using rongeurs or osteotomes. If an oscillating saw is used, the surgeon should be especially diligent about water cooling the site and preventing heat-induced osteonecrosis (**TECH FIG 5B**).
- If a humpback deformity (flexion of the scaphoid through the nonunion site) is identified, a 1.1-mm K-wire should be placed in the proximal and distal poles to act as joysticks to correct the deformity prior to grafting and final fixation.
- If the nonunion site is expansive, the proximal and distal poles should be packed with cancellous autograft from the bone flap harvest site prior to insertion of the flap and definitive fixation.
- Osteosynthesis can be completed with a headless compression screw advanced from the proximal or distal pole, depending upon the orientation of the nonunion site.
 - Alternatively, K-wires may be used upon the surgeon's preference.
- The dorsal capsule is carefully closed with an absorbable suture, such as a 3-0 poliglecaprone-25 or polyglactin suture. The extensor retinaculum is closed with similar 3-0 suture, leaving the extensor pollicis longus superficial to the retinaculum.
- Depending upon the volume of expected postoperative edema and skin quality, the skin is closed with either deep dermal stitches and a running subcuticular or simply vertical mattress stitches with 4-0 nylon.
- The wrist is immobilized in a well-padded plaster short-arm spica splint.

TECH FIG 5 • A. Scaphoid waist chronic fibrous nonunion with osteolysis. **B.** Preparation of the scaphoid prior to bone grafting, with resection of all fibrous and necrotic bone as visualized by bleeding tissue. Note restoration of the scaphoid distal pole extension from flexion (“humpback deformity”) and the resultant bone void.

PEARLS AND PITFALLS

Scaphoid preparation

- Degeneration of the radioscapoid facet or post-traumatic arthrosis may predispose to ongoing pain and stiffness and should be considered a potential contraindication to scaphoid salvage techniques.
- A radial styloidectomy can be performed as an adjunctive technique in the setting of mild radioscapoid arthrosis or to prevent impingement of the vascular pedicle to the bone flap (**FIG 3**).

- A posterior interosseous neurectomy with distal transection, proximal crush, and transposition may be used during the initial exposure.
- The adherent capsular tissue on the dorsal ridge of the scaphoid should be carefully preserved, as this may represent the blood supply to the scaphoid.
- Following insertion of the bone flap, a 0.8-mm K-wire can be placed just dorsal to the flap to prevent migration or extrusion during application of a compression screw.

4 + 5 ECA; 1,2-ICSRA

- If prior dorsal capsulotomies have been made, the arterial pedicle may have been transected, rendering the 4 + 5 ECA vascularized bone flap unreliable.
- Depending upon the width of the dorsal distal radius, the fourth or fifth ECA may be selected. However, great care should be utilized to prevent violation of the distal radioulnar joint or sigmoid notch when osteotomizing the fifth ECA-based bone flap as it is more ulnarly placed.
- The 4 + 5 ECA bone flap must be osteotomized and elevated prior to full capsular exposure of the scaphoid; therefore, the surgeon should be aware of the potential dimensions of the flap based on preoperative imaging and design the osteotomies to be ample. In comparison, the 1,2-ICSRA should be identified and protected prior to the dorsal radiocarpal capsulotomy, but the bone flap does not need to be osteotomized and elevated prior to exposure of the scaphoid.
- Osteotomies should be made at least 1 cm proximal to the radiocarpal joint to avoid penetration or disruption of the radiocarpal facets.
- Undue traction or injury on the superficial dorsal radial sensory nerve may lead to increased or prolonged postoperative pain.

MFC

- Iatrogenic injury to the saphenous nerve should be avoided by careful identification to the neighboring saphenous artery branch and elevation of the nerve from the proposed skin paddle.
- The skin component is usually elevated first, and attention is then turned to the bone segment. This is because posterior bone cuts will not be readily accessible until the skin paddle and the DGA-CB are reflected in an anterior direction.

FIG 3 • Intraoperative image following resection of the radial styloid and proximal scaphoid pole with preservation of the scaphocapitate articulation.

POSTOPERATIVE CARE

- The patient is placed in a well-padded thumb spica splint. At 2 weeks, the splint and stitches are removed and a thumb spica cast is applied.
- Casting is typically continued for a total of 10 to 12 weeks, with cast changes at 3- to 4-week intervals.
- The authors advocate burying K-wires under the skin, since they are usually left in for 6 weeks. Buried wires can be removed in the office or operating room once union is verified. Exposed K-wires should be removed near 3 to 4 weeks to prevent pin site infections and possible bacterial colonization of the nonunion site.
- X-rays should be obtained at each postoperative visit. CT scans can be obtained at the surgeon's discretion, but the authors recommend 10 to 18 weeks postoperatively to determine extent of union (**FIGS 4 to 6**).
- Osseous union is identified by bridging trabeculae on radiographs and absence of fracture site tenderness.

FIG 4 • Osseous union following MFC vascularized bone flap to the scaphoid waist. The dorsal branch of the radial artery at the wrist was used for inflow to the descending geniculate artery.

OUTCOMES

- Vascularized bone grafting of the scaphoid demonstrates union rates near 90%.⁸
- Across 6 studies (23.1%) involving 124 subjects following vascularized bone grafting to the scaphoid, preoperative pain was 5.20 and postoperative pain was 0.99 (on a 10-point scale), a 79.2% improvement. Two studies (7.69%) used Bach's criteria of pain and activity (BCPA) and Bach's criteria of pain activity limitation (BCPAL).⁹ Across 34 patients, the BCPA improved from 4.32

preoperatively to 1.96 postoperatively, a 54.6% improvement; the BCPAL improved from 4.21 preoperatively to 1.77 postoperatively, a 57.9% improvement.

- Across all studies, regardless of metric, postoperative pain was improved at least 50% after vascularized bone grafting.

FIG 5 • A–C. Radiograph and CT scans showing chronic scaphoid nonunion, with cyst formation and osteolysis. **D–F.** Osseous union is seen following dorsal vascularized fourth + fifth extensor compartmental artery flap and compression screw.

FIG 6 • Osseous union of the proximal scaphoid pole following medial femoral trochlea vascularized bone flap and compression screw.

- Previous studies have demonstrated that the ability to return to work and gainful employment have a significantly positive effect on the perceived health, physical function, and thus quality of life for individuals after injury.
- Vascularized bone grafting serves as a viable option to restore the normal anatomy of the radiocarpal joint and thus re-establish a patient's overall functionality.⁶

COMPLICATIONS

- The most common complication is superficial wound or pin site infection, nerve irritation, and complex regional pain syndrome (1.25%).
- Immediate postsurgical complications are typically only seen in microvascular cases with flap circulatory collapse.

- Errant osteotomies could potentially result in iatrogenic fracture of either the femur or distal radius.

Open Reduction and Fixation of Acute Perilunate Fracture Dislocation

20

CHAPTER

Grant M. Kleiber and Amy M. Moore

DEFINITION

- Perilunate dislocation refers to a pattern of ligamentous injuries and/or fractures involving the carpus. In a perilunate dislocation, the lunate remains in its anatomic position, and there is dorsal dislocation of the carpus in relation to the lunate.
- In a lunate dislocation, the lunate is volarly displaced outside of the lunate facet.
- Lesser arc injury refers to a purely ligamentous injury pattern.
- Greater arc injury implies at least one fracture in addition to the perilunate dislocation, the most common being the scaphoid and radial styloid.
- In the event of a greater arc injury, the injury pattern and the fractures are described using the nomenclature “trans-[fractured bone]” in addition to “perilunate dislocation.” For example, a perilunate dislocation with a radial styloid and scaphoid fracture would be described as a “transradial styloid, trans-scaphoid perilunate dislocation.”

ANATOMY

- The carpus is constrained by a network of dorsal and volar radiocarpal (extrinsic) and intercarpal (intrinsic) ligaments (**FIG 1**).
- The lunate is constrained by extrinsic ligaments on its volar surface only: the long radiolunate, short radiolunate, and ulnolunate ligaments.
- The lunate is constrained by intrinsic intercarpal ligaments on its radial and ulnar edges: the scapholunate and lunotriquetral ligaments.
- The scapholunate ligament is strongest at its dorsal aspect, whereas the

lunotriquetral ligament is strongest at its volar aspect.

- The space of Poirier is an area of weakness in the volar wrist capsule, allowing the midcarpal joint to expand and contract during wrist motion. It is located between the radioscaphocapitate and the long radiolunate ligaments (see **FIG 1**).

PATHOGENESIS

- The biomechanical forces resulting in a perilunate dislocation are wrist hyperextension, ulnar deviation, and intercarpal supination.
- In a dorsal perilunate dislocation, there is rupture of the scapholunate and lunotriquetral ligaments, causing the carpus to dislocate dorsally off of the lunate.
- The lunate protrudes through the volar wrist capsule through the space of Poirier.

FIG 1 • A: The volar ligaments of the wrist include from radial to ulnar: radioscaphocapitate (RSC), long radiolunate (LRL), short radiolunate (SRL), ulnolunate (UL), and lunocapitate (UC), which overlies the ulnocapitate. Distally, the triquetrohamate and triquetrocapitate ligament stabilize the ulnar carpus (THC). The space of Poirier lies proximal to the arc

between the radial and ulnar volar ligaments. **B:** The dorsal ligaments include the dorsal intercarpal ligament (DIC) and dorsal radiocarpal ligament (DRC).

FIG 2 • The Mayfield classification of perilunate injuries proposes a radial-to-ulnar progression of injury. In stage I, the scapholunate ligament is ruptured. Stage II is disruption of the capitulunate articulation. Stage III is disruption of the lunotriquetral ligament and dorsal dislocation of the carpus from the lunate. Stage IV is volar dislocation of the lunate out of the lunate fossa of the radius.

- The short radiolunate ligament typically remains intact in a perilunate dislocation, tethering the volar lunate to the volar lip of the radius.
- Mayfield classified perilunate dislocations as a progression of injury from radial to ulnar around the lunate¹ (**FIG 2**):
 - Stage I: Scapholunate disruption with rotation of scaphoid
 - Stage II: Capitulate dissociation
 - Stage III: Lunotriquetral ligament rupture, dislocation of carpus dorsal to lunate
 - Stage IV: Lunate dislocation: lunate is dislocated volarly out of the lunate fossa.
- In a greater arc injury, there is transmission of force through the bony

structures surrounding the lunate, resulting in at least one fracture in addition to the perilunate dislocation (**FIG 3**).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically report a high-energy injury such as a fall from height or a motor vehicle collision.
- A full trauma workup should be initiated depending on the mechanism of injury.

FIG 3 • A lesser arc injury refers to a purely ligamentous pattern of injury, as described in the Mayfield classification. A greater arc injury describes the injury pattern traveling through at least one bony structure, such as the radial styloid, scaphoid, capitate, triquetrum, or ulnar styloid.

- Patients may present with acute carpal tunnel syndrome, with symptoms ranging from paresthesias to severe burning pain in their median-innervated digits.

- The examiner should perform a complete neurovascular examination of the hand including two-point discrimination to document sensory disturbance.
- The wrist is evaluated for edema, gross deformity, and tenderness.
 - Ecchymosis and edema over the volar wrist are often seen.

IMAGING

- Standard three-view wrist radiographs (PA, lateral, oblique) are sufficient for diagnosis in most cases.
- AP views demonstrate irregularity of the carpal rows, with a triangular lunate silhouette superimposed over other bones (**FIG 4A**).
- Lateral views shows the lunate tipped volarly relative to the remainder of the carpus in a “spilled teacup” sign (**FIG 4B**).
- In trans-scaphoid perilunate injuries, the displaced scaphoid proximal pole is seen attached to the lunate (**FIG 4C,D**).
- A CT scan may be helpful to identify and characterize carpal fractures in greater arc perilunate dislocations. Ideally, this study would be performed after reduction of the carpus.

DIFFERENTIAL DIAGNOSIS

- Scapholunate dissociation
- Scaphoid fracture
- Radiocarpal dislocation

NONOPERATIVE MANAGEMENT

- Closed reduction of the lunate should be attempted in all patients using the Tavernier maneuver (**FIG 5**).
- Conscious sedation is recommended for patient comfort and relaxation—facilitating reduction.
- The Tavernier maneuver:
 - The wrist is extended and the lunate is palpated volarly with the examiner’s thumb.
 - Axial traction is placed on the patient’s wrist, and gentle pressure is applied to the volar aspect of the lunate.
 - The wrist is then flexed forward while maintaining axial traction and volar pressure on the lunate. Successful reduction is often accompanied by a palpable “clunk.”
 - Wrist radiographs are taken in traction to verify reduction, and a sugar tong

splint is applied.

- If reduction is unsuccessful, an open reduction should be performed in the operating room in an urgent manner.

FIG 4 • A. AP radiograph of a perilunate dislocation demonstrates disruption of carpal rows and a triangle-shaped lunate (L) superimposed over the midcarpal joint. **B.** Lateral radiograph of a perilunate dislocation demonstrates dorsal translation of the carpus off the lunate, which is flexed forward. In this case, the lunate remains located within the lunate fossa of the radius. **C.**

AP radiograph of a trans-scaphoid perilunate dislocation. The triangular shape of the lunate and disruption of the carpal arcs are demonstrated. **D.** Lateral radiograph demonstrates that in a trans-scaphoid perilunate dislocation the proximal pole of the scaphoid remains attached the lunate. The remainder of the carpus is dislocated dorsally. T, trapezium; Tr, trapezoid; C, capitate; H, hamate; S, scaphoid; Tq, triquetrum; R, radius; U, ulna.

FIG 5 • The Tavernier's maneuver consists of (1) applying distal traction on the wrist while stabilizing the lunate with the opposite thumb. (2) The wrist is then extended and volar pressure is applied on the lunate to prevent dislocation into the carpal tunnel. (3) With traction and the lunate stabilized, the distal carpal row is reduced over the lunate into position with gentle wrist flexion.

SURGICAL MANAGEMENT

- If successful closed reduction is achieved, operative intervention and reconstruction can be performed several days later as a scheduled procedure but ideally within 1 week.
- Irreducible dislocations must be treated urgently to prevent median nerve impingement and devascularization of the lunate and displaced carpal bones.
- A surgical option for irreducible dislocations or for less experienced hand surgeons taking call is to take the patient to the operating room urgently for the volar approach to the carpus. An extended carpal tunnel release is performed to decompress the median nerve followed by open reduction of the carpus and repair of the volar lunotriquetral ligament and capsule. The dorsal approach can then later be performed by surgeons with expertise in the wrist.

Preoperative Planning

- As discussed previously, careful neurological exam should be performed including two-point discrimination to determine the baseline median nerve function.
- Any surgical equipment, such as hardware or suture anchors, should be available.
- A perilunate dislocation can be performed under regional or general anesthesia.

Positioning

- The patient is positioned supine with affected arm on a radiolucent hand table centered on the patient's axilla.
- A well-padded pneumatic tourniquet is placed on the upper arm.
- If an assistant is not available to assist with traction, end table traction with finger traps and 5 to 10 lb of weight will facilitate dissection and reduction during the procedure.

Approach

- A combined dorsal and volar approach is recommended for perilunate dislocations.
- Dorsal approach
 - A 6- to 8-cm longitudinal incision centered over ulnar aspect of the Lister tubercle between the third and fourth extensor compartments provides good exposure. The radiocarpal and midcarpal joints are then exposed using a ligament-sparing capsulotomy, splitting the dorsal radiocarpal and dorsal

intercarpal ligaments (**FIG 6**).²

- The dorsal approach is required in all patients for ligament repair and stabilization.
- Volar approach
 - A standard carpal tunnel release incision is extended across the wrist crease in a zigzag fashion for 2 to 3 cm.
 - The volar approach adds the benefit of open reduction of the lunate under direct visualization, volar lunotriquetral ligament repair, volar capsular repair, and median nerve decompression via the extended carpal tunnel release.

FIG 6 • A dorsal ligament-sparing capsulotomy splits the dorsal radiocarpal (DRC) and dorsal intercarpal (DIC) ligaments, maintaining their fibers in continuity for added dorsal stabilization of the wrist with closure. (From Berger RA, Bishop AT. A fiber-splitting capsulotomy technique for dorsal exposure of the wrist. *Tech Hand Up Extrem Surg.* 1997;1:2-10.)

TECHNIQUES

■ Lesser Arc Perilunate Dislocation

Volar Approach with Extended Carpal Tunnel Release and Open Reduction

- An extended carpal tunnel incision is made, crossing at least 2 to 3 cm proximal to the wrist crease.
- The transverse carpal ligament is divided along its ulnar aspect to avoid the median nerve, which may be displaced due to presence of the lunate within the carpal tunnel. As the carpal tunnel is released, blood is typically seen in this space.
- The antebrachial fascia is released proximally under direct vision, and the median nerve and flexor tendons are retracted radially.
- The lunate is visualized within the carpal tunnel, protruding from the volar wrist capsule and typically in a flexed position (**TECH FIG 1**). It is gently reduced into its anatomic position with axial traction on the wrist and gentle extension and pressure on the lunate.
- The volar lunotriquetral ligament is visualized and is repaired with nonabsorbable suture.
- The crescent-shaped tear in the volar wrist capsule is also repaired with nonabsorbable suture.

Dorsal Approach with Ligament Repair

Exposure

- The wrist is approached dorsally through a 6- to 8-cm incision centered on the ulnar aspect of the Lister tubercle via the third and fourth extensor compartments.
- Blunt dissection is carried over the extensor retinaculum to raise subcutaneous flaps radially and ulnarly. The radial sensory nerve and dorsal cutaneous branch of the ulnar nerve are identified and protected throughout the case.
- The extensor retinaculum is incised over the EPL tendon, which is transposed out of the retinaculum.

- The extensor retinaculum is then raised off of the fourth dorsal compartment and the second dorsal compartment, entering each through the open third compartment. Self-retaining retractors are placed, exposing the wrist capsule.
- A ligament-sparing capsulotomy is performed to enter the wrist joint, splitting the fibers of the dorsal radiocarpal ligament and the dorsal intercarpal ligament. A radially based capsular flap is raised by extending the proximal incision radially along the dorsal radius (**TECH FIG 2**).^{2,3}
- The scaphoid, lunate, and triquetrum are visualized. Dorsal remnants of the scapholunate and lunotriquetral ligaments are identified. Typically, the ligaments are torn asymmetrically, with a larger piece on one side of the joint.

TECH FIG 1 • On volar approach to the wrist, the lunate (L) is seen protruding into the carpal tunnel through a crescent-shaped rent in the volar wrist capsule.

Reduction and Fixation

- Suture anchors are inserted in preparation for ligament repair. The anchor is inserted to the side of the joint with the smaller ligament fragment, so the sutures may be passed through the larger fragment.
- Fluoroscopic imaging and direct visualization are used to ensure adequate placement of the anchors.

- The scaphoid is typically found to be flexed, and the lunate is extended. To correct the scapholunate angle, a 0.062-in. K-wire is inserted into the dorsum of the scaphoid and the lunate to act as a joystick.
- Using the K-wire joysticks, the scaphoid and lunate are aligned under lateral fluoroscopy to restore a scapholunate angle of 40 to 55 degrees (**TECH FIG 3A**). The K-wires can be provisionally secured together with a hemostat to hold this reduction.
- Another option is to place a radiolunate K-wire to hold the reduced lunate in place and then the scaphoid can be reduced to the lunate using the K-wire joystick (**TECH FIG 3B**).
- The sutures attached to the anchors are now passed through the scapholunate and lunotriquetral ligaments and left untied until intercarpal pins are placed.
- Intercarpal pins are placed using 0.045-in. K-wires. Pins are placed to stabilize the scapholunate interval and the lunotriquetral interval.

TECH FIG 2 • Using a ligament-sparing capsulotomy,

a radially based capsular flap is raised to expose the carpus. (From Berger RA, Bishop AT. A fiber-splitting capsulotomy technique for dorsal exposure of the wrist. *Tech Hand Up Extrem Surg.* 1997;1:2-10.)

- A scaphocapitate pin is placed to stabilize the scaphoid from flexing (**TECH FIG 3C**). Pins are buried beneath the skin to avoid pin-tract infection that invariably will occur when pins are left outside the skin for more than a few weeks.
- AP and lateral fluoroscopic radiographs are taken to ensure adequate reduction of the SL and LT interval, and a scapholunate angle of 40 to 55 degrees (**TECH FIG 3D**).
 - If these films are satisfactory, the suture anchors are tied down.
- The wrist is irrigated copiously with normal saline to ensure no remaining osteochondral debris is present in the articular space.
- The capsulotomy, followed by the extensor retinaculum, is then closed with nonabsorbable sutures.

TECH FIG 3 • A. The scapholunate angle is restored using 0.062-in. K-wire joysticks placed into the lunate and scaphoid. These can be secured together with a

hemostat to hold the reduction temporarily. **B.** Another option is to reduce the lunate and then place a radiolunate K-wire to stabilize the lunate. The scaphoid can then be reduced to the lunate to restore the scapholunate angle using a joystick. **C.** AP radiograph demonstrates that the carpus is stabilized with 0.045-in. K-wires after suture anchors have been placed for reconstruction of the ligaments. Two K-wires are placed in the scapholunate and lunotriquetral intervals. A scaphocapitate (and/or a triquetrocipitate) K-wire can also be placed to stabilize the capitoulunate joint if found to be unstable. **D.** Lateral view of carpus after K-wire stabilization and ligament repair demonstrates restoration of acceptable scapholunate angle.

■ Repair of Greater Arc Injury

Trans-scaphoid Perilunate Dislocation

- Greater arc injuries result in a fracture of an adjacent bone accompanying the perilunate dislocation. The scaphoid is the most common bone involved (**TECH FIG 4A,B**).
- The same volar and dorsal approaches are used as outlined above.
- The scapholunate ligament is most often intact in a trans-scaphoid perilunate dislocation (**TECH FIG 4C**), and the proximal pole of the scaphoid is displaced with the lunate (see **FIG 4D**).
- The scaphoid fracture is reduced under direct vision, aligning the cartilaginous surface of the scaphoid.
 - Joystick K-wires can be placed in the proximal and distal poles to aid in reduction and stabilization.
 - The scaphoid is fixated with a dorsal cannulated compression screw using standard technique, with the caveat that the fracture will be less stable than typical scaphoid fractures.
- Use of distal radius bone graft is encouraged if significant comminution of

the scaphoid is found. The graft can be easily taken from under the Lister tubercle in the same exposure.

- A guidewire is placed for a cannulated screw along the axis of the scaphoid, beginning proximally at the center of the membranous portion of the scapholunate ligament
- An antirotation parallel wire should be placed alongside the guidewire to stabilize the scaphoid fracture for overdrilling the guidewire.
- Most cannulated screw systems have a parallel wire guide for placement of this wire. This step is highly recommended due to the instability of the fracture.

TECH FIG 4 • A. AP radiograph demonstrates a trans-scaphoid perilunate dislocation. In this greater arc injury, there is a scaphoid (S) waist fracture instead of a scapholunate ligament injury. **B.** The proximal pole of the scaphoid remains attached to the lunate (L) and flexes with it. **C.** Image of right wrist demonstrates scaphoid fracture with intact scapholunate ligament (*). **D and E.** AP and lateral radiographs of open reduction and fixation of a trans-scaphoid perilunate injury with K-wire stabilization of the carpus and cannulated screw fixation of the scaphoid. C, capitate; R, radius Tq, triquetrum.

TECH FIG 5 • AP radiograph of a greater arc transradial styloid, trans-scaphoid, transcapitate perilunate dislocation. The distal radius fracture was treated with fragment-specific fixation, and cannulated screws were to repair the capitate and scaphoid fractures.

- The guidewire is measured and overdrilled, and an appropriately sized cannulated compression screw is placed over the wire.
- A scaphocapitate K-wire can be placed to further stabilize the lunocapitate joint as well as reinforce the scaphoid fixation if comminuted.
- The lunotriquetral ligament is repaired with suture anchors in the same manner described above, and the lunotriquetral interval is pinned with 0.045-in. K-wires (**TECH FIG 4D,E**).

Transradial Styloid, Trans-scaphoid, Transcapitate Perilunate Dislocation

- Greater arc injuries result in a fracture of an adjacent bone accompanying the perilunate dislocation. The scaphoid is the most common bone involved, and the technique for fixation of a trans-scaphoid perilunate is outlined above.
- Radial styloid fractures involving greater than one-third of the scaphoid fossa should be repaired to stabilize the volar ligamentous attachments.⁴ This can be performed with cannulated screw fixation or a radial column pin plate. Anatomic alignment of the articular surface is critical.
- Transverse capitate fractures may be managed with cannulated compression screws, allowing the screws to be buried beneath the articular surface (**TECH FIG 5**).

Perilunate Dislocation Reconstruction with Posterior Interosseous Neurectomy

- The terminal branch of the posterior interosseous nerve (PIN) runs in the floor of the fourth dorsal compartment. It provides sensory innervation to the wrist joint.
- Perilunate dislocation and its subsequent reconstruction result in significant capsular trauma to the wrist joint. A PIN neurectomy should be strongly considered as an adjunctive procedure to decrease postoperative pain and improve long-term outcomes.
- The PIN can be consistently found 3 to 4 cm proximal and 1 cm ulnar to Lister tubercle, beneath the tendons of the fourth dorsal compartment.
- The nerve is carefully dissected free from the artery for a distance of 2 to 3 cm. The nerve is crushed proximally with a hemostat and distally 1 to 2 cm is resected. The proximal nerve is then cauterized.
- The proximal nerve end is transposed proximally along the course of the nerve, burying it beneath the forearm musculature to prevent symptomatic neuroma formation.

PEARLS AND PITFALLS

Irreducible perilunate dislocation

- A closed reduction should be attempted in the emergency room under sedation.
- If unable to reduce, open reduction should be performed in the

	operating room in an urgent fashion to decompress the median nerve and improve vascular supply to the displaced carpus.
Median nerve compression	■ Acute carpal tunnel syndrome commonly accompanies perilunate dislocation. These patients should be treated with urgent median nerve decompression and relocation of the lunate through a volar approach. ■ Carpal tunnel release should be performed in all patients due to trauma to the median nerve from the perilunate dislocation.
Technique: Ligament repairs	■ Suture anchors can be use to repair the scapholunate and/or lunotriquetral ligaments. ■ The anchors should be placed prior to the reduction and K-wire fixation of the interval to allow best visualization. ■ Once the interval is reduced and stabilized with K-wires, the sutures can be tied and secured.
Scapholunate angle	■ A normal scapholunate angle between 30 and 60 degrees should be restored, ideally between 40 to 55 degrees. ■ Place joystick K-wires into the scaphoid and lunate to extend the scaphoid and flex the lunate into an anatomic position (see TECH FIG 3A). ■ The lunate can also be stabilized with a temporary radiolunate pin (see TECH FIG 3B).
Posterior interosseous neurectomy	■ A PIN neurectomy should be strongly considered at the time of ligament repair to decrease postoperative pain. ■ The nerve is found in the floor of the fourth dorsal compartment.

POSTOPERATIVE CARE

- The patient is placed in a sugar tong splint for 2 weeks, followed by 8 to 10 weeks of thumb spica cast immobilization.
- K-wires are removed at 8 to 10 weeks. Burying pins beneath the skin results in fewer issues with pin-tract infections, but they may require removal in the OR.
- Gentle range of motion exercises are begun after K-wire removal. Hand therapy is initiated to regain wrist motion.
- A protective removable splint is worn between therapy sessions until pain and range of motion has stabilized. For greater arc injuries, the splint is worn until union is achieved.

OUTCOMES

- Patients should expect decreased wrist range of motion, particularly flexion

and extension, after this significant injury (**FIG 7**). Near-normal pronosupination is typically restored.

- Total arc of motion for flexion/extension is reported from 57% to 83% of the contralateral side.^{5–10}
- A recent retrospective review of 65 cases reported that 85% of patients were able to return to their previous occupation.⁵
- Despite adequate fixation and intervention, most patients (range 18%–92%) develop radiographic signs of radiocarpal and midcarpal arthrosis over time.^{6,11}
- In a study by Forli et al.,⁶ 67% of their patients developed post-traumatic degenerative changes; however, they report that the arthrosis is well tolerated at an average follow-up of 13 years.
- Proximal row carpectomy can be considered as a secondary salvage procedure in patients with avascular necrosis of the lunate or in delayed unrecognized perilunate dislocation.¹²

COMPLICATIONS

- Multiple complications can result from the severe wrist trauma at the time of injury, as well as, from the operative procedure itself.
- Complex regional pain syndrome has been reported to occur in up to 12% of patients.⁵
- K-wire/pin-tract infections can occur.
- Osteonecrosis of lunate or scaphoid has been reported at rate of about 8%.⁵
- Carpal bone nonunion such as in trans-scaphoid perilunate dislocation is rare.^{6,9}

FIG 7 • At 6 months postoperatively, functional extension (**A**) and flexion (**B**) have been restored. However, range of motion is decreased compared to

the uninjured hand.

Dorsal Capsulodesis for Scapholunate Stabilization with Extensor Carpi Radialis Longus Tenodesis

21

CHAPTER

Mark Morris and Kevin C. Chung

DEFINITION

- Scapholunate (SL) dissociation is the most common cause of carpal instability.
- SL dissociation can result in static or dynamic carpal instability.
 - Static instability: Radiographic changes are seen on standard wrist radiographs.
 - Dynamic instability: Standard radiographs are normal, but signs of instability are seen on stress radiographs.
- Partial SL interosseous ligament tears do not produce radiographic changes and often require arthroscopy for diagnosis.
- SL dissociation left untreated leads to dorsal intercalated instability (DISI) and eventually scapholunate advanced collapse (SLAC).¹

ANATOMY, PATIENT HISTORY, AND PHYSICAL FINDINGS, IMAGING

- See Chapter 15 in the Hand section.

SURGICAL MANAGEMENT

- Dividing the SL interosseous ligament leads to altered radiocarpal kinematics and causes abnormal radiocarpal and ulnocarpal pressure distributions.^{2,3}
- The radioscapoid joint is normally congruent. However, when the scaphoid is subluxed because of SL instability, the load is shifted and abnormal contact points are created, leading to degenerative changes (**FIG 1**).⁴

- The goal of dorsal capsulodesis and extensor carpi radialis longus (ECRL) transfer is to maintain the extended position of the scaphoid in order to restore normal carpal alignment and avoid abnormal radiocarpal contact pressures that otherwise lead to pain and degenerative changes.
- Capsulodesis alone is contraindicated if there is static SL dissociation, whereas ECRL tendon transfer can be performed with static SL dissociation as long as reduction is possible in the operating room. Either procedure is contraindicated if radiocarpal or midcarpal degenerative changes are present.
- Capsulodesis is indicated for predynamic SL instability secondary to an isolated partial SL ligament tear (seen on arthroscopy) and for dynamic SL instability with intact secondary stabilizers and a technically repairable dorsal capsule.
- The main advantage of dorsal capsulodesis over tendon transfer is the technical ease of the procedure.
 - The disadvantage of dorsal capsulodesis is the predilection for attenuation of the repair over time and progressive carpal collapse.⁵ Tendon transfer provides increased strength of repair and the ability to maintain reduction of the scaphoid over time.
 - Additionally, with a capsulodesis, the scaphoid is theoretically still unstable through much of the arc of wrist motion until it reaches the limit of flexion set by the capsulodesis. In contrast, a dynamic transfer should provide an extension force to the scaphoid throughout the entire range of wrist motion.⁶
- ECRL transfer to the scaphoid can be used as an alternative to capsulodesis for treatment of a partial SL ligament tear. ECRL transfer can be performed if the capsule is not technically repairable, which would obviously preclude capsulodesis.
- The ECRL tendon transfer was designed to re-establish a fluid scaphoid slider-crank motion and restore midcarpal kinematics without tethering the scaphoid or limiting wrist flexion.
 - A slider-crank mechanism converts linear motion to rotatory motion or vice versa, such as with a piston and crank shaft of an engine.

FIG 1 • A. Normal orientation of the scaphoid and radius shows a congruent articulation between the scaphoid and the scaphoid facet of the radius. **B.** An area of abnormal loading of the radioscaphoid joint occurs when the scaphoid undergoes rotary subluxation. Disproportionate loading of the joint leads to degenerative changes.

- The slider-crank model of the wrist described by Linscheid et al.⁷ explains wrist kinematics as a three-bar linkage composed of the radius, lunate, and capitate. The three bars are stabilized by the scaphoid, which acts as the crank. When the wrist is extended, the scaphoid “crank” causes dorsal rotation of the lunate by a dorsally directed compressive force. With flexion, the scaphoid causes flexion of the lunate via a palmarly directed tensile force (**FIG 2**).

- ECRL tendon transfer provides a consistent extension force to the scaphoid throughout the range of motion, as opposed to a dorsal capsulodesis, which acts merely as a checkrein to flexion of the scaphoid. By doing so, the scaphoid is able to influence the kinematics of the wrist throughout the arc of motion rather than just at the point limited by the checkrein.

FIG 2 • The slider-crank model of the wrist joint posits a three-bar link between the radius, lunate, and capitate, with the scaphoid acting as the crank. The *red arrows* show the direction of force produced by the crank mechanism—a dorsally directed compressive force with extension of the wrist and a palmarly directed tensile force with flexion of the wrist.

Preoperative Planning

- Wrist arthroscopy has become the standard method of evaluation of interosseous ligament injuries. Geissler grading of ligament injuries as seen during arthroscopy is as follows⁸:
 - Grade 1: Attenuation/hemorrhage of interosseous ligament as seen from the radiocarpal joint. No incongruency of carpal alignment in the midcarpal space.
 - Grade 2: Attenuation/hemorrhage of interosseous ligament as seen from the radiocarpal joint. Incongruency/step-off as seen from the midcarpal space. A small gap may be seen between the carpal bones but smaller than the width of a probe.
 - Grade 3: Complete ligament tear seen from the radiocarpal joint. Incongruency/step-off of carpal alignment is seen from both the radiocarpal and midcarpal spaces. The probe can be passed through the gap between carpal bones.
 - Grade 4: Complete ligament tear is seen from radiocarpal joint. Incongruency/step-off of carpal alignment is seen from both the radiocarpal and midcarpal spaces. Arthroscope (2.7 mm) can be passed through the gap in the carpal bones. Gross instability with manipulation.

Positioning

- The patient is positioned supine on the operating table. The operative arm is on a hand table.
- Regional or general anesthesia can be used.
- A tourniquet is applied.
- An examination under anesthesia is performed to check for instability.

Approach

- A dorsal approach to the wrist is utilized, centered over the Lister tubercle (**FIG 3**).
- The third dorsal compartment is identified but does not need to be opened in most cases.
- Dissection is performed between the second and fourth compartments to expose the scaphoid and lunate.

FIG 3 • A dorsal incision is centered over the Lister tubercle.

TECHNIQUES

■ Dorsal Capsulodesis for Scapholunate Instability Using Suture Anchors

Exposure

- A 6-cm dorsal longitudinal incision is made, centered over the radiocarpal joint in line with the long finger metacarpal.
- Sharp dissection is carried down to the extensor retinaculum.
- Skin and subcutaneous tissue flaps are raised.
- The second and fourth compartments are elevated such that the tendons are maintained within the compartment.
- The wrist capsule is incised longitudinally to expose the scaphoid and lunate.
- The remaining dorsal SL ligament is assessed (**TECH FIG 1**).

Reduction

- Two 0.062-in. K-wires are placed into the dorsal scaphoid and lunate to act as joysticks for reduction.
- The scaphoid wire is retracted proximally to extend the scaphoid. The lunate wire is retracted distally to flex the lunate.
 - Fluoroscopy is used to evaluate the reduction.
- The assistant holds the scaphoid and lunate reduced using the joystick K-

wires while the surgeon drills one K-wire percutaneously from the radial side of the wrist, through the scaphoid and lunate.

TECH FIG 1 • Exposure of the SL joint in this patient shows an intact dorsal SL ligament (*arrow*). This patient had normal wrist radiographs, and SL diastasis on wrist arthroscopy.

- A second K-wire is then drilled through the scaphoid into the capitate to prevent the scaphoid from rotating. This will hold the reduction.

Fixation

- A curette is used to debride the cortical bone from the distal dorsal scaphoid until cancellous bone is visible. This will provide a more favorable environment for healing the capsule to bone.
- Drill a hole using the Mitek anchor drill into the most distal part of the dorsal scaphoid. The drill hole should be placed adjacent to the scaphotrapezial joint, distal to the scaphoid axis of rotation. Place a 1.8-mm suture anchor (mini Mitek or similar) into the drill hole.
- Secure the dorsal capsule to the scaphoid by passing the suture from the

anchor through the overlying capsule. Tie the suture securely to prevent the scaphoid from flexing.

- Final fixation is assessed fluoroscopically to confirm that the lunate is in neutral position and the carpal bones are aligned correctly (**TECH FIG 2**).
- The dorsal capsule is repaired using 3-0 Ethibond suture.

Closure

- The tourniquet is released and hemostasis is obtained.
- The extensor retinaculum is closed with 3-0 Ethibond suture.
- Skin is closed with a 4-0 Monocryl suture.

TECH FIG 2 • Postoperative AP and lateral radiographs show a suture anchor in the dorsal scaphoid and a K-wire traversing the SL joint.

■ Scapholunate Stabilization with Dynamic ECRL Tendon Transfer

Exposure and Reduction

- The skin incision is centered over the dorsal wrist joint between the third and fourth dorsal compartments and extends from the Lister tubercle proximally

to between the index and long finger metacarpal bases distally.

- Expose the ECRL and extensor carpi radialis brevis (ECRB) from the distal edge of the extensor retinaculum to their insertions on the index and long finger metacarpal bases, respectively.
- The extensor tendons are retracted ulnarly to expose the wrist capsule. The wrist capsule is incised longitudinally, just radial to the origin of the dorsal radiocarpal (DRC) ligament proximally and radial to the insertion of the dorsal intercarpal (DIC) ligament distally. This will expose the SL joint and the SL ligament tear.
- Reduce the scaphoid and lunate and pin in place, as described above in the capsulodesis section.

Tendon Transfer

- Prepare the ECRL tendon insertion site at the dorsal distal scaphoid (**TECH FIG 3A,B**).
- A trough is made the dorsal distal scaphoid in the same manner as described in the capsulodesis section, and one or two mini Mitek anchors are placed.
- Anchors can alternatively be placed after the tendon is harvested.
- To harvest the ECRL tendon, it is incised transversely from its insertion on the dorsal base of the second metacarpal (**TECH FIG 3C**).
- The tendon tension should be set to a length that will make it isotonic when docked into the scaphoid—the tendon transfer should provide equal tension to the scaphoid throughout the arc of wrist motion.
 - If the tendon is too short, tension will be too high with wrist flexion.
 - If the tendon is too long, tension will be too light with wrist extension.
- Any adhesions are released so the ECRL has full excursion.
- To secure the tendon transfer, extend the wrist and have the assistant retract the tendon distally to reach the scaphoid while the surgeon ties the tendon down tightly to the anchor. The tendon can otherwise retract during this step.

TECH FIG 3 • **A,B.** AP and lateral depictions of the ECRL insertion site in the scaphoid. The *red circles* indicate the area of the dorsal distal scaphoid to be curetted. **C.** The ECRL graft is harvested from the base of the second metacarpal. The *red circle* shows the location of the docking hole. The red line indicates where to transect the ECRL tendon from the insertion site on the index metacarpal base.

- Use two mini Mitek anchors for more secure attachment (**TECH FIG 4**).

Closure

- The dorsal wrist capsule is closed with 3-0 Ethibond suture.
- The tourniquet is released and hemostasis is achieved prior to further closure.
- Skin is closed with a 4-0 Monocryl suture.

TECH FIG 4 • Two mini Mitek anchors secure the ECRL tendon graft, which pulls the scaphoid back into extension.

PEARLS AND PITFALLS

Technique

- When placing joystick K-wires, correction of the deformity will be easier if the scaphoid wire is directed proximally and the lunate wire is directed distally.
- When drilling a hole for a suture anchor, care must be taken to protect the vascular pedicle that inserts at the dorsal ridge of the scaphoid.
- We recommend cutting K-wires under the skin to avoid pin-tract infection. Infection is common when K-wires are left outside of

	the skin for more than 3 weeks.
Postoperative care	■ Wrist range of motion is expected to decrease by about 20%. Despite this, most patients have significant improvement in pain after this surgery.
Rehabilitation	■ Patients are instructed to avoid forceful axial loading of the wrist (especially activities like weight lifting or push-ups) for 6 months.

POSTOPERATIVE CARE

- Postoperatively, the patient is placed into a volar wrist splint for 8 weeks.
 - For capsulodesis, the wrist can be splinted in a neutral position.
 - After dynamic ECRL transfer or tenodesis, the wrist is splinted in 15 to 20 degrees of extension to prevent excessive tension at the ECRL insertion site.
- The wound is examined and sutures are removed (if nonabsorbable sutures are used) after 10 days.
- The K-wires are removed 6 to 8 weeks after the initial surgery.
- After 8 weeks of splinting, the patient is transitioned to a removable volar splint for an additional 4 weeks. Gentle active wrist range of motion can begin at this time.

OUTCOMES

- Dorsal capsulodesis
 - Gajendran et al.⁹ studied 16 wrists in 15 patients who were treated with dorsal capsulodesis for chronic, flexible, static SL dissociation with follow-up of greater than 60 months (average 86 months). At final follow-up, average wrist flexion and extension were 50 and 55 degrees, respectively. Outcomes were also measured with disabilities of the arm, shoulder, and hand (DASH; average score 19), Short Form-12 (average score 78), and Mayo wrist score (average 78). Mayo scores were “excellent” in 38%, “good” in 19%, “fair” in 31%, and “poor” in 12% of patients. Grip strength was statistically unchanged from preoperative to final follow-up. Radiographs at final follow-up showed an average SL angle of 62 degrees, and an SL gap of 3.5 mm. Fifty percent of wrists (8/16) had evidence of arthritis on radiographs. Radiographic outcome did not correlate with subjective pain scores. The authors concluded that although dorsal capsulodesis did not prevent arthritic changes, patient satisfaction and functionality remained high after this surgery.
 - Megerle et al.⁵ did a retrospective study of 59 patients who underwent dorsal capsulodesis, with a mean follow-up of 8.25 years (4.3–12 years). Although

carpal alignment was significantly improved immediately postoperatively, results at long-term follow-up showed a return to preoperative alignment (mean SL angle 70 degrees at final follow-up). Eight patients required a salvage procedure at 2.33 years, and 40 patients had radiographic evidence of arthritis at final follow-up. Mean DASH and Mayo wrist scores were 28 and 61, respectively. The authors concluded that although capsulodesis did not prevent degenerative changes, most patients had acceptable clinical outcomes at long-term follow-up.

- ECRL tenodesis: Bleuler et al.¹⁰ studied 20 patients who were treated with dynamic ECRL tenodesis. All but one patient were satisfied with the functional outcome at short-term follow-up and would undergo the same surgery again if they had the choice. All patients were able to return to their former occupation between 1.5 and 4 months postoperatively.
- Combined ECRL tenodesis with dorsal capsulodesis: De Carli et al.¹¹ retrospectively reviewed 8 wrists in 8 patients who underwent combined ECRL tenodesis-capsulodesis for static SL dissociation with a minimum follow-up of 1 year (average 23 months). Average visual analog scale score (VAS: 0–10) postoperatively was 3. The mean DASH score was 13. Functional results were “excellent” in 2 cases and “good” in 6 cases. All patients lost some of their initial reduction on radiographs, but none had recurrence of carpal collapse.

COMPLICATIONS

- Infection
- Chronic regional pain syndrome
- Damage to the superficial radial nerve
- Loss of wrist range of motion
- Pin-tract infection
- Fracture

CHAPTER Proximal Row Carpectomy

Patrick Reavey and Amy M. Moore

DEFINITION

- First described by Stamm,¹ proximal row carpectomy (PRC) is the removal of the scaphoid, lunate, and triquetrum, resulting in a neoradiocarpal articulation between the proximal capitate and the lunate fossa of the radius.
- PRC is one of the “motion-preserving” options for the treatment of degenerative carpal arthritis.

ANATOMY

- The proximal carpal row consists of the scaphoid, lunate, and triquetrum, and the distal carpal row includes the trapezium, trapezoid, capitate, and hamate (**FIG 1A**).
- Removal of the proximal carpal row converts a complex link joint to a simple hinge joint between the capitate and distal radius.
- Differences in the capitate and lunate morphology have been described as possible reasons for failure of PRC. However, biomechanical and clinical outcome studies have not demonstrated a significant relationship between carpal shape and failure.^{2,3}
- The carpal bones are linked to the radius and ulna and to each other by a complex network of extrinsic and intrinsic ligaments.
 - The radioscaphocapitate (RSC) ligament extends from the radial styloid across the volar waist of the scaphoid to the capitate (**FIG 1B**).
 - Identifying and preserving this ligament during PRC is crucial to prevent ulnar subluxation of the remaining carpus.

PATHOGENESIS

- A number of conditions can lead to painful radiocarpal arthritis.
- Scapholunate advanced collapse (SLAC) and scaphoid nonunion advanced collapse (SNAC) occur secondary to chronic scapholunate (SL) ligament disruption and scaphoid fracture nonunion, respectively.
 - Both of these conditions result in progressive radiocarpal arthritis that starts between the radial styloid and scaphoid.
 - In later stages, these conditions can progress to a pancarpal arthritis and may involve the lunocapitate joint.
- Kienbock disease is an idiopathic avascular necrosis of the lunate that can lead to varying degrees of intercarpal and radiocarpal arthritis.
- Treatment for each of these conditions varies based on the etiology and stage of disease at presentation. However, once significant arthritis has developed, conservative measures including splinting and steroid injections can minimize pain and improve function.

FIG 1 • A. Diagram of the carpus. **B.** Location of volar radioscaphocapitate ligament.

Table 1 Radiologic Staging Systems of Common Degenerative Wrist Arthritidis

Radiographic Stage	Kienboch's	SLAC	SNAC
1	No visible	<i>Arthritis between</i>	<i>Arthritis between</i>

	changes on x-ray, decreased vascularity on MRI	<i>scaphoid and radial styloid</i>	<i>scaphoid and radial styloid</i>
2	Sclerosis of lunate	<i>Arthritis between scaphoid and entire scaphoid facet of radius</i>	<i>Stage 1 + scaphocapitate arthritis</i>
3	A: lunate collapse, no scaphoid rotation B: lunate collapse, fixed scaphoid rotation	<i>Arthritis between capitate and lunate^a</i>	<i>Periscaphoid arthritis</i>
4	<i>Degenerated adjacent intercarpal joints^a</i>	Pancarpal arthritis	

Italics indicate stages appropriate for treatment with PRC.

^aLunocapitate arthritis is a contraindication to PRC, though capsular interposition or osteochondral resurfacing modifications may be performed in the presence of arthritis.

Kienbock, Lichtman classification; SLAC, Watson classification.

- PRC is usually reserved as a salvage operation for patients who have failed surgical treatment of earlier stages of the disease and have also failed trials of conservative management.^{4,5} Table 1 covers staging of each condition and indications for PRC.
- PRC has also been described in the acute treatment of severe radiocarpal or carpal fracture dislocations⁶ but is not recommended in the initial treatment of early SL dissociations.⁷

NATURAL HISTORY

- Carpal arthritis frequently presents with patients complaining of wrist pain, decreased range of motion and grip strength, and inability to perform daily activities without discomfort.
- Many patients will have a distant history of trauma or prior surgical procedures for an acute injury.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Preoperative evaluation of a patient with wrist arthritis should include a detailed history, an assessment of functional limitations, measurement of wrist range of motion, and grip strength.
- History
 - A patient's occupation, age, and interests are key factors in determining if PRC is an appropriate procedure.
 - PRC is generally indicated in patients older than 40 who have low physical demands.
 - Younger patients and manual laborers have less ideal outcomes and higher failure rates after PRC.^{3,8}
 - The operative records from prior surgeries should be obtained and the outcome of any trial of conservative therapy should be elicited.
 - Use of a patient-reported outcome measure (PROM) such as the Michigan Hand Questionnaire (MHQ), disability of the arm, shoulder, and hand (DASH), or Patient-reported Wrist Evaluation (PRWE) can be helpful in determining the patient's baseline functional disability and following postoperative outcomes.
- Physical examination
 - The skin is evaluated for scarring and/or previous incisions.
 - The wrist is evaluated for edema, gross deformity, and tenderness.
- Range of motion and grip strength
 - Active wrist flexion and extension as well as radial and ulnar deviation are measured with the forearm in neutral rotation.
 - Total range of motion as well as the extent of each motion at which the patient experiences pain is determined.
 - Grip strength is measured with a dynamometer.
 - The bilateral wrist measurements are obtained and compared.
- Carpal examination
 - A detailed examination of the carpus is performed to elicit sites of discomfort to palpation and motion.
 - Evaluating for snuffbox tenderness, SL tenderness, and a Watson's is useful when determining the primary pathology leading to carpal arthritis but does not directly impact the decision to perform a PRC.
- Neurovascular examination
 - The examiner should perform a complete neurovascular examination of the

hand.

IMAGING

- Standard three-view wrist radiographs (PA, lateral, oblique) are performed to evaluate for the extent of carpal arthritis.
- Specific evaluation of the lunocapitate joint on PA view is crucial to determining if PRC is an option for the patient because arthritic change at this joint precludes performing a PRC when a normal capitate is needed to articulate with the lunate fossa on the radius.
 - If there is any evidence of lunocapitate arthritis on x-ray, modifications of a PRC may be required (see below in techniques).
 - The patients should also be counseled that they may require conversion to an alternative procedure (ie, wrist fusion) intraoperatively.
- CT scan or MRI may be helpful in evaluating the pathologies that lead to carpal arthritis or the presence of synovitis in the intercarpal joints. However, they are not required prior to performing a PRC as the capitate can be visualized directly early in the procedure with options to perform alternative salvage procedures if necessary.

NONOPERATIVE MANAGEMENT

- Painful radiocarpal arthritis can initially be treated with splinting and/or steroid injections.

SURGICAL MANAGEMENT

- PRC is considered an appropriate salvage procedure if nonoperative measures fail or do not provide durable pain relief.
- Alternative salvage procedures include limited or total wrist arthrodesis.

Preoperative Planning

- As discussed above, evaluating the lunocapitate articulation helps in determining if a patient is a candidate for PRC.
- Mild arthritis of the proximal capitate may not be visualized on radiographs, so all patients should be counseled that they may require conversion to a limited wrist fusion intraoperatively.
- Any implants required for wrist fusion should be available in case they are needed.
- PRC can be performed under regional or general anesthesia.

Positioning

- The patient is positioned supine with the hand over a radiopaque hand table centered on the patient's axilla.
- A well-padded pneumatic tourniquet is placed on the upper arm.
- If an assistant is not available to assist with traction, end-table traction with finger traps and 5 to 10 lb of weight will facilitate dissection during the procedure.

Approach

- A dorsal radiocarpal approach between the third and fourth extensor compartments provides good exposure to inspect the radiolunate and lunocapitate articulations, remove the proximal carpal row, as well as to perform modifications to the PRC procedure or other salvage procedures.
- A volar approach has also been described; however, this requires partial division and subsequent repair of the crucial RSC ligament.⁹ This approach also limits options for alternative salvage procedures and is not recommended by the authors.
- A PRC can be performed arthroscopically,^{10,11} though this requires significant experience with these techniques and may not have long-term benefit to patients when compared to the standard procedure.⁵
- The key steps of a standard PRC are described below. Two modifications of PRC that can be performed in the setting of limited proximal capitate arthrosis are also described.

TECHNIQUES

■ Standard Proximal Row Carpectomy

Exposure

- Exsanguinate the arm with Esmarch tourniquet and inflate the pneumatic tourniquet.
- Make a dorsal longitudinal incision approximately 8 cm in length over the carpus just ulnar to the Lister tubercle (**TECH FIG 1A**).
- Raise subcutaneous flaps ulnarly and radially just above the extensor retinaculum to protect sensory branches of the superficial radial and dorsal

ulnar nerves.

- Identify the extensor pollicis longus (EPL) tendon proximal or distal to the retinaculum and divide the retinaculum sharply along the third dorsal compartment (**TECH FIG 1B**). Externalize and retract the EPL radially so that the EPL does not rupture with swelling around the Lister tubercle after surgery.
- Raise the fourth compartment off the distal radius ulnarly in a subperiosteal fashion, with care not to injure the dorsal ligaments.
- Identify the extensor carpi radialis brevis (ECRB) tendon and place a Weitlaner to retract the ECRB and EPL tendons radially and the fourth dorsal compartment ulnarly.

Capsulotomy

- To enter the carpus, a longitudinal capsulotomy can be made in line with the division between the third and fourth dorsal compartments.
- However, designing an L-shaped capsulotomy provides good exposure for carpectomy and preserves the dorsal capsule for use in an interposition flap if needed (see below).

TECH FIG 1 • A. Incision for dorsal exposure of the carpus. *Circle marks the Lister tubercle.* **B.** Exposure of extensor retinaculum after raising subcutaneous flaps. The retinaculum is divided along the third compartment (*dashed line*).

TECH FIG 2 • A. Markings for L-shaped capsulotomy (solid line). The *dashed line* indicates an incision to convert the capsulotomy into a distally based flap for capsular interposition. **B.** The capsular flap is raised and retracted to expose the carpus (*white arrow*). A portion of the dorsal cuff of capsule has been raised contiguous with the floor of the fourth compartment (*yellow arrow*). L, lunate; S, scaphoid; C, capitate.

- The longitudinal incision should be in line with the native position of the ECRB and connect to a capsular incision along the radiocarpal joint extending ulnarly.
- Leave a small cuff of capsule on the distal radius (**TECH FIG 2A**).
- Use a knife to raise the dorsal capsule off the carpal bones to completely expose the carpus (**TECH FIG 2B**).
- Once the carpus is exposed, inspect the lunate fossa of the radius and the proximal pole of the capitate for arthrosis.
 - If there is some arthrosis of the capitate, a modified PRC may be possible (see below).
 - In the setting of significant arthrosis, PRC should be aborted and the surgical plan changed to limited or complete wrist fusion.
- Once the decision is made to proceed with PRC, the proximal carpal bones are resected.

Bone Removal

- Place the patient's hand under traction with the help of an assistant or finger traps attached to weights off the end of the hand table. This aids in exposure and creates space between the carpal rows as well as the radius.
- Removal of the proximal row can be done in any order—scaphoid first or scaphoid last. However, there is more room for “error” during removal of the triquetrum, so surgeons with less experience may want to start with the triquetrum excision.
- The general steps to remove each bone is as follows:
 - First, divide any intact dorsal intrinsic ligaments to facilitate independent mobilization of each bone.
 - Use a penetrating towel clamp (or place small threaded Steinman pins or K-wires into the bones) to help manipulate each bone during dissection. Pins are especially useful in the setting of SNAC wrist to separately manipulate and dissect around the proximal and distal poles of the scaphoid.
 - Use a Carroll elevator to bluntly begin the dissection around the volar aspect of each bone. A scraping sensation, as if dissecting subperiosteally, indicates the proper plane.
 - Once enough of the attachments are released, the bone can be torqued to directly visualize the volar ligaments. At this point, sharp dissection with a knife can be used to release the ligaments directly off the bone.
 - Piecemeal resection of the lunate and triquetrum (ie, with a rongeur or osteotome) is acceptable, but not advisable because it makes grasping and manipulating the bones difficult during final volar dissection. Thus, this technique is not recommended for the scaphoid.
- Key aspects of lunate excision:
 - It is crucial not to damage the cartilage on the proximal capitate and lunate fossa of the radius during lunate excision.
 - Hohmann retractors (or similar) should not be used around the lunate during dissection.
 - Consistent traction will provide space to ease dissection around the lunate.
 - Two wet 4 × 4 gauze can be tucked into the lunate fossa and around the proximal capitate to protect these cartilaginous surfaces during removal.
- Key aspects of scaphoid excision:
 - Slow and meticulous dissection along the volar waist of the scaphoid is

imperative to preserve the RSC ligament.

- Until each ligament is clearly visualized, all dissection along the scaphoid should be done bluntly.
- Once the scaphoid has been removed, the intact RSC ligament should be visualized crossing from the radial styloid to the capitate (**TECH FIG 3**).

Completion and Closure

- After completing the carpectomy, fluoroscopy should be used to ensure complete resection. Small, retained portions of the distal scaphoid may not be symptomatic postoperatively,⁵ but any other bone fragments should be removed.

TECH FIG 3 • The proximal row has been resected. Note the thick radioscaphocapitate ligament in the volar capsule (*white arrow*). With forced ulnar translation, the capitate (C) does not migrate past the lunate fossa of the radius.

- Stress the carpus ulnarly to test the volar radiocarpal ligaments.
- If the RSC ligament is adequately preserved, the capitate should not translate past the lunate fossa.
- If the carpus does translate ulnarly, the RSC ligament was likely compromised and the pinning of the neoradiocarpal joint is recommended.

- Seat the capitate into the lunate fossa.
 - Repair the dorsal capsulotomy with a 4-0 absorbable suture.
 - Repair the extensor retinaculum with 4-0 suture leaving the EPL externalized, ie, transposed.
 - Let down the tourniquet and check for hemostasis.
 - A layered skin closure with a running subcuticular 4-0 suture (absorbable or non-absorbable) leaves a minimal scar.
 - Patients are placed into a volar resting splint for postoperative comfort.
-

■ Proximal Row Carpectomy with Wrist Denervation

- Neurectomy of the posterior and anterior interosseous nerves may decrease postoperative pain and improve long-term outcomes.⁸
- Denervation can be completed at the beginning or end of the case.
- The tendons of the fourth dorsal compartment are isolated proximal to the extensor retinaculum and retracted ulnarly (**TECH FIG 4A**).
 - The posterior interosseous nerve and artery can be identified on the floor of the fourth dorsal compartment.
 - The nerve is carefully dissected away from the artery, crushed proximally, and resected for a length of 1 to 2 cm. The proximal nerve end is then cauterized.
- The extensor tendons are then shifted radially and the interosseous membrane just proximal to the distal radioulnar joint is identified.
 - A 2- to 3-cm incision is made on the interosseous membrane and the anterior interosseous nerve and artery are identified just volar to the cut membrane (**TECH FIG 4B**).
 - The nerve is crushed proximally, and a 1- to 2-cm length of the nerve is resected with cauterization of the ends.
- After resection of the nerves, the procedure continues as described above.

TECH FIG 4 • A. The posterior interosseous nerve (*white arrow*) is seen on the floor of the fourth compartment, which is retracted ulnarly (*yellow arrow*). **B.** A longitudinal incision has been made in the interosseous membrane (*circled*) and the anterior interosseous nerve is seen immediately below (*white arrow*). The fourth compartment remains retracted ulnarly (*yellow arrow*).

■ Proximal Row Carpectomy with Capsular Interposition

- The Salomon-Eaton modification of the PRC uses a dorsal capsular flap, which is interposed between the capitate and radius and can be performed in the setting of proximal capitate arthritis.^{4,5,12}
- The procedure is performed the same as the standard PRC; however, it is required to perform the initial dorsal capsulotomy so that a distally based capsular flap can be used (see **TECH FIG 2A**).
- After exposure of the capitate and presence of arthritis is confirmed, the proximal row is removed in the same manner as a standard PRC.

TECH FIG 5 • A. The proximal capitate is resected flush with the base of the hamate. **B.** The distally based dorsal capsular flap is sutured around the distal carpal bones to the volar capsule.

- In the traditional Salomon-Eaton procedure, the proximal capitate is then resected with a sagittal saw or osteotome to the level of the hamate (**TECH FIG 5A**). However, resection of the proximal capitate is not required for flap interposition and may result in deleterious injury to the remaining capitate and/or proximal hamate. The authors recommend leaving the capitate as is prior to flap interposition.
- The dorsal L-shaped capsulotomy is converted into a distally based rectangular flap by creating a longitudinal incision in the capsule on the ulnar aspect of the capitate.
- The dorsal flap is then sutured around the proximal capitate to the volar capsule with 4-0 nonabsorbable suture (**TECH FIG 5B**).
- A 0.062-in. K-wire is then inserted in a retrograde fashion from the capitate to the radius to secure it in the lunate fossa.
- As there is no dorsal capsule to close with this technique, closure begins with repair of the extensor retinaculum and proceeds in the standard fashion.

■ Proximal Row Carpectomy with Osteochondral Grafting

- This modification of PRC is indicated for resurfacing limited arthritis (less than 10 mm) of the proximal capitate.¹³ The procedure uses an osteochondral graft harvested from one of the removed carpal bones that is placed into the proximal capitate articular surface.
 - The procedure begins as in the standard PRC.
 - Once the capitate is inspected and found to have a small area of cartilage loss (less than 10 mm), osteochondral grafting can be performed.
 - The proximal row is removed as in the standard PRC; however, at least one of the bones must be removed en bloc to harvest the osteochondral graft.
 - Once the proximal row is removed, the size of the cartilage defect in the capitate is determined and resected with a reamer for a depth of 10 mm.
 - A harvesting dowel of matching diameter is then used to harvest a full-thickness osteochondral graft from one of the removed bones in an area of pristine cartilage, usually on the lunate or triquetrum.
 - The graft is cut down to 10 mm in length and then gently impacted into the defect in the proximal capitate until the cartilage surface is flush.
 - Closure proceeds in the same fashion for a standard PRC.
-

PEARLS AND PITFALLS

Patient selection

- PRC has the longest durability in older patients (older than 40 years) with low physical demands.

Planning

- Patients with evidence of lunocapitate arthritis on radiographs should not be offered PRC.
- Designing the L-shaped capsulotomy in all patients reserves the dorsal capsule interposition flap as a bail-out in cases with mild arthritis encountered intraoperatively.

Technique

- Blunt dissection around the scaphoid is crucial to preserve the RSC ligament.
- Failure to preserve this ligament may lead to poor alignment of the

	capitate and lunate fossa and early failure of the procedure.
Technique	■ Avoid damage to the proximal capitate and lunate fossa of the radius during removal of the proximal row.
Therapy	■ Early motion postoperatively allows for quicker return to of motion without any adverse outcomes.

POSTOPERATIVE CARE

- Patients are seen in the office 2 weeks after surgery and the splint and sutures removed.
- Standard radiographs of the wrist are obtained to confirm appropriate alignment of the radiocapitate articulation (**FIG 2**).
- Patients in whom the RSC was protected and have maintained alignment can begin an early protected range of motion protocol.^{14,15}
- Strengthening of the wrist is reserved until 6 to 8 weeks postoperatively.

OUTCOMES

- Postoperative pain from PRC generally takes 3 to 6 months to resolve.^{3,4,16} However, once recovered, nearly all patients will note a significant decrease in their preoperative pain, and this continues to improve during the first postoperative year.
- Patients can expect to regain between 50% and 85% of their contralateral wrist flexion-extension arc and 75% to 90% of grip strength relative to their contralateral side.^{3-5,8,16,17}
 - Though the range of motion may be less than preoperatively, the decrease in patient's pain provides greater use of the hand, and most patients are extremely satisfied with the results of PRC.
 - Relative to alternative salvage procedures such as four-corner arthrodesis, PRC demonstrates better flexion and extension, though less radial deviation and grip strength.^{12,18}
- Long-term follow-up of PRC patients more than 10 years demonstrates a 10% to 15% failure rate with these patients requiring revision surgery for wrist arthrodesis.^{3-5,8,16,17,19}
 - Younger patients (younger than 40 years of age) and manual laborers have a higher rate of failure,^{3,5} though some authors report that 90% of high-demand patients are still able to function in their occupational capacity.^{15,16,19}
 - All patients will end up with arthritis at the neoradiocarpal joint. However,

most patients will still have good clinical outcomes that do not correlate with the degree of arthritis.^{3-5,8,13,16,19}

- Overall, the results of capsular interposition and osteochondral resurfacing during PRC are similar to those in standard PRC.^{4,5,13}

COMPLICATIONS

- The advantage of PRC is that it has a low complication rate and does not require bony union as in the alternative salvage wrist limited fusion procedures.
- Improper selection of patients may lead to higher failure rates.
- By far the most common complication of PRC is failure to preserve the RSC ligament during dissection. This requires prolonged immobilization postoperatively and leads to a higher likelihood of failure.

FIG 2 • Postoperative **(A)** PA and **(B)** lateral radiographs of a patient after proximal row carpectomy. Note the appropriate alignment of the capitate in the lunate fossa of the radius.

Section V: Distal Radius Fractures

23

CHAPTER **Distal Radius Fractures**

Shoshana W. Ambani and Kevin C. Chung

DEFINITION

- Distal radius fractures encompass all fractures of the articular and distal metaphyseal components of the distal radius.
- They are the most common fracture of the human skeleton, with an annual incidence of over 640 000 cases in the United States.
- These fractures have a bimodal distribution, with peak occurrences in the 5- to 14-year-old and 75- to 84-year-old populations.
- Fractures of the distal radius distort the normal radiocarpal configuration, changing the biomechanical properties of the wrist joint.
- Nonanatomic alignment due to displaced fractures may lead to degenerative arthritis in the long term.

ANATOMY

- The distal radius has three concave articular surfaces: the scaphoid fossa, lunate fossa, and sigmoid notch (**FIGS 1** and **2A**).
- The dorsal aspect of the distal radius is convex and acts as a fulcrum for the extensor mechanism (**FIG 2B**).
- The extensor pollicis longus tendon passes ulnar to the Lister tubercle, a dorsal landmark on the distal radius.

FIG 1 • The distal radius.

- Hand and forearm tendons and musculature are shown in **FIG 3**, and the extensor compartments of the wrist and anatomy of the dorsal wrist capsule are shown in **FIG 4**.
- Important anatomic considerations with regard to surgery of the distal radius are further delineated in the Techniques section of this chapter.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically present with tenderness, swelling, and deformity of the wrist after a fall. Such a fall leads to compressive loading on the extended wrist.
 - The term FOOSH, which stands for “fall on outstretched hand,” is a commonly used acronym describing this mechanism.
- Often, the wrist is described as having a “dinner fork deformity” upon examination (**FIG 5**).
- It is important to perform a comprehensive hand and wrist examination while paying particular attention to any median nerve symptoms that would indicate

the presence of acute carpal tunnel syndrome.

FIG 2 • Volar (A) and dorsal (B) surface anatomy of the distal radius.

FIG 4 • Dorsal (A) and cross-sectional (B) views of the six extensor compartments of the wrist. C. Anatomy of dorsal wrist capsule.

FIG 3 • Tendons and muscles of the dorsal forearm and hand **(A)** and the distal volar forearm and wrist **(B)**.

FIG 5 • Dinner fork deformity.

- Any open injuries should be noted and require urgent debridement.
- The distal ulna should be examined for dorsal prominence or instability, which may be indicative of a concomitant distal ulna fracture or a tear of the

triangular fibrocartilaginous complex (TFCC) ligament.

- The elbow should be examined for tenderness at the radial head and collateral ligaments. Tenderness in this location may be indicative of a radial head fracture, elbow dislocation, or other elbow-related injury requiring attention.

IMAGING

- Standard imaging for all wrist injuries include posteroanterior (PA), oblique, and lateral radiographs.
- On PA view, the distal radius has an average slope of 22 degrees in the radial-to-ulnar plane (radial inclination), with a radial height of about 10 to 12 mm (**FIG 6A**). The congruity of the distal radius articulation with the ulna at the sigmoid notch, as well as the radiocarpal joint itself, must be assessed.
- On lateral view, the distal radius tilts about 12 degrees in the dorsal-to-volar plane (volar tilt) (**FIG 6B**).

FIG 6 • A. Distal radius radial length and radial angulation. **B.** Distal radius volar tilt.

- If significant intra-articular comminution is present, a computed tomography (CT) scan may provide more information on the location and displacement of fracture fragments to aid in preoperative planning.

DIFFERENTIAL DIAGNOSIS

- Distal radius fractures can be differentiated from other wrist injuries, including the following, by careful examination and review of imaging.
 - Wrist sprain or contusion
 - Radiocarpal dislocation
 - Carpal bone fracture or dislocation, including fractures of the scaphoid
 - Carpal ligament injury, including injury to the scapholunate ligament
 - Fracture of the distal ulna or ulnar styloid
 - Distal radioulnar joint (DRUJ) injury
 - Degenerative arthritis
 - Inflammatory arthritis
 - Septic arthritis
 - Crystalloid arthropathy
- It is important to rule out other concomitant injuries, such as an acute median neuropathy.

CLASSIFICATION SYSTEMS AND EPONYMS

- Once diagnosed, distal radius fractures should be classified as open or closed, displaced or nondisplaced, and extra-articular or intra-articular. The structural elements and angles should be further described for clarity of the fracture pattern.
- Several classification systems exist for distal radius fractures, including the Muller AO, Frykman, Melone, Rayhack, Mayo Clinic, and universal classification systems. Given the plethora of independent classification systems, their use may complicate communication about fracture patterns. It is preferable to describe the fracture pattern directly.
- Eponyms were traditionally used to describe particular distal radius fractures but now only have historical significance. Common eponyms and nicknames include the following (**FIG 7**):
 - A Colles fracture is an extra-articular distal radius fracture featuring an apex

volar deformity with dorsal comminution.

- A Smith fracture, or “reverse” Colles fracture, is an extra-articular distal radius fracture with an apex dorsal configuration.
- A die-punch fracture is an intra-articular depression fracture of the lunate fossa of the distal radius, resulting from a direct load transmitted through the lunate.
- A Barton fracture is an intra-articular shear fracture of the distal radius, involving a fracture dislocation of the radiocarpal joint, either volarly or dorsally.
- A Hutchinson fracture, or “chauffeur’s fracture,” is an isolated intra-articular fracture of the radial styloid. Chauffeurs often sustained injuries from manual crank starters that backfired.

INITIAL MANAGEMENT

- The goal of treating distal radius fractures is to achieve anatomic reduction, thereby maintaining wrist biomechanics.
- Initial management of any distal radius fracture requires closed reduction and immobilization.

FIG 7 • Eponyms and nicknames for distal radius fractures.

- This can be done with the use of a “hematoma block,” in which local anesthetic such as 1% lidocaine is injected dorsally into the fracture site. In addition, providing the patient with a benzodiazepine can help with muscle relaxation, thus minimizing deforming forces.
- The chance of success can be improved further with the use of continuous intravenous sedation, which provides better muscle relaxation than does a single benzodiazepine dose.

- The patient's index and middle fingers are then placed in finger traps suspended from an IV pole, with the shoulder abducted 90 degrees and elbow flexed at 90 degrees (**FIG 8A**). Weights are applied to the patient's elbow for traction (usually 5 to 15 lb), thereby distracting the fracture site.
- If necessary, a maneuver recreating the injury mechanism to disimpact the fracture site can be performed, followed by a reduction maneuver (**FIG 8B**).
- Notably, with simple distraction and sedation, the fracture often autoreduces without significant manipulation.
- A mini C-arm is employed to determine the adequacy of closed reduction in real time.
- Once reduction is achieved, with the patient still in finger traps, a sugar-tong splint is applied to stabilize the fracture site by preventing wrist flexion-extension and supination-pronation.
- Postreduction films are imperative.

FIG 8 • A. General setup for closed reduction of a distal radius fracture. **B.** Reduction maneuver for dorsal displaced distal radius fractures. First, the wrist joint is placed in traction. Then, the physician's thumb is used to push the distal fragment volarly into alignment.

- If closed reduction is successful, strict immobilization over the next 6 to 8 weeks can lead to adequate fracture healing, obviating the need for surgery.

- An unstable fracture will not be maintained in a splint, however, and surgery should be considered pending patient circumstances.

NONOPERATIVE MANAGEMENT

- Nonoperative management consists of splinting or casting of stable fracture patterns. These are typically nondisplaced or minimally displaced fractures, or fractures that are well reduced.
- The patient's age, medical comorbidities, and functional level should be considered in determining whether or not to pursue nonoperative management vs surgical intervention.
- Patients being treated nonoperatively should be monitored with weekly radiographs for loss of reduction.
 - A volar tilt of 0 to 11 degrees dorsal tilt, radial shortening of 5 mm, and articular incongruity of 1 mm can be tolerated.
- Typically, the patient can be switched to a short-arm cast at 2 to 3 weeks for the remainder of the healing period.
- Early range of motion (ROM) of nonimmobilized joints is essential to prevent contracture. The cast should not extend past the metacarpophalangeal joints to allow finger ROM.

SURGICAL MANAGEMENT

- The goal of treatment is to restore anatomical alignment, thereby maintaining normal wrist biomechanics and decreasing the risk of developing degenerative arthritis.
- Indications for surgery include but are not limited to
 - Articular incongruity more than 1 to 2 mm
 - Radial shortening more than 5 mm
 - Dorsal tilt more than 10 to 20 degrees
 - Extensive comminution
 - Open fractures

Preoperative Planning

- Patient comorbidities must be assessed.
- Healthy patients are often given a regional block with intravenous sedation by the anesthesia team.
- Imaging should be thoroughly reviewed to develop a concrete operative plan.
- If the patient presents with median nerve symptoms, a concomitant carpal

tunnel release should be considered.

FIG 9 • Hand table setup.

Positioning

- Procedures on the distal radius are done on a hand table, with the surgeon seated (**FIG 9**).
- The patient is positioned supine on the operating bed as near to the hand table as possible.
- A tourniquet is placed on the upper arm.

Approach

- Surgical options for the treatment of distal radius fractures include percutaneous Kirschner wire (K-wire) fixation, external fixation, volar plate fixation, dorsal plate fixation, and dorsal bridge plate fixation.
- Percutaneous pinning with K-wires is indicated for unstable, displaced extra-articular distal radius fractures, simple intra-articular distal radius fractures, and displaced distal radius fractures in children and adolescents.
- External fixation uses ligamentotaxis to reduce and stabilize fracture fragments. Indications include unstable, irreducible extra-articular fractures, displaced intra-articular fractures that can be reduced in a closed or percutaneous fashion, and highly comminuted fractures that are openly reduced and fixed with plates or pins but require further carpal unloading to promote

healing. External fixation can be used as an adjunct to other fixation techniques should further stabilization be required.

- Volar-locking plate fixation is indicated for unstable, displaced extra-articular fractures, displaced intra-articular fractures, and volar shearing fractures. The introduction of volar-locking plating techniques has revolutionized the treatment of distal radius fractures by allowing early return of activity and by avoiding the problems of dorsal plating.
- Dorsal plating can be difficult in the presence of dorsal comminution and is associated with a higher rate of postoperative extensor tendon injury, adhesion, or rupture. Dorsal plate fixation is generally reserved for dorsal shear fractures or lunate facet fractures involving the dorsal cortex.
- Dorsal bridge plate fixation is designated for highly comminuted, intra-articular distal radius fractures, including those associated with significant metaphyseal and diaphyseal comminution, in particular subsets of patients:
 - Polytrauma patients with impaired ability to conduct activities of daily living
 - Patients who refuse external fixation for psychological or aesthetic concerns
 - Patients with extensive tendon injuries that will require multiple procedures followed by soft tissue and bony healing over an extended period of time
 - Patients with severe osteoporosis
 - For patients with osteoporosis and severe comminution of the distal radius, the bridging plate serves as an internal distractor that permits healing of the comminuted bone while giving the patient the latitude for self-care, with the bridging plate stabilizing the wrist.
 - At 2 to 6 months, when the distal radius has healed, the plate is removed and the patient can initiate wrist motion to regain mobility.

TECHNIQUES

■ Percutaneous Pinning

Equipment

- A tourniquet is not usually needed, although some surgeons advocate for its use to minimize soft tissue swelling during the procedure, thereby allowing improved palpation of bony landmarks.
- The pins are typically 0.062 in. K-wires, which are driven into bone using a

power hand drill (**TECH FIG 1**).

- An intraoperative C-arm is required to assess fracture configuration and pin placement throughout the procedure.

Procedure

- We prefer the intrafocal Kapandji technique for percutaneous pinning of distal radius fractures, particularly if the bone is osteopenic and brittle.
- A K-wire is introduced dorsally into the fracture site as a lever to restore volar tilt (**TECH FIG 2A,B**).

TECH FIG 1 • A power hand drill is used to insert K-wires.

TECH FIG 2 • The Kapandji intrafocal technique. **A.** A K-wire is placed dorsally into the fracture site. **B.** The

distal fragment is levered volarly with the K-wire to achieve reduction. **C,D.** AP and lateral fluoroscopic intraoperative views showing placement of the pins. **E.** K-wire pins in place.

- Once fracture reduction is achieved, one or two more K-wires are driven into the intact volar cortex at the same level, thereby buttressing the reduction. In a similar manner, the fracture can be levered radially to restore radial inclination.
- This is followed by placement of an additional buttressing K-wire.
- Once the fracture is stabilized by this buttressing technique, traditional pinning from the radial styloid and from the dorsoulnar aspect of the radius through the fracture fragments can proceed (**TECH FIG 2C–E**).

Postoperative Care

- Patients are seen 2 weeks postoperatively in clinic for splint takedown, dressing change, and suture removal.
- A removable volar splint is applied.
- Gentle finger, wrist, and elbow ROM is allowed at this time.
- Serial x-rays are obtained at clinic visits to ensure stable bony alignment.
- In adults, K-wires are removed in the office at 5 to 6 weeks.
 - In pediatric patients, K-wires can be removed as early as 4 weeks, depending on radiographic and clinical signs of healing.
- Pin-track infection can lead to early removal of the pin, and if the infection is not treated or recognized, deep osteomyelitis can cause devastating problems.
 - Patients must be taught to clean the pin site meticulously twice a day with hydrogen peroxide on a cotton-tip applicator and then to seal the pin entry site with bacitracin ointment.

■ External Fixation

Equipment

- A variety of external fixator systems for treatment of distal radius fractures exist through different manufacturers. The surgeon must select an external fixator, and the instruction manual must be studied prior to use in the

operating room.

- A tourniquet is useful to help maintain hemostasis during the procedure, particularly if done in conjunction with internal fixation.
- A C-arm is required intraoperatively to assess fracture configuration and pin placement.

Pertinent Anatomy

- The external fixator is placed parallel to the dorsoradial surface of the wrist, using pins at the proximal and distal ends.
 - The distal pins are placed in the second metacarpal.
 - The proximal pins are placed in the radial shaft, approximately 10 cm or one hand's breadth proximal to the radial styloid. This is the location of the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) muscles as they traverse the radial shaft.
- One must have a solid understanding of the dorsal hand and forearm tendons and musculature (see **FIG 3A**) and the extensor compartments of the wrist (see **FIG 4A**).

Fracture Reduction

- The forearm is pronated on the hand table.
- The fracture is first reduced under fluoroscopic guidance.
- Percutaneous 0.062 in. K-wires may be placed dorsally as well as through the radial styloid to help maintain the reduction (**TECH FIG 3**).

Pin and External Fixation Frame Placement

- A 2-cm longitudinal incision is made dorsoradially just proximal to the APL and EPB tendons, about a hand's breadth proximal to the radial styloid.
 - Care is taken to visualize and protect the superficial radial nerve in this area.
- The first pin of the external fixator is inserted into the radial shaft in the deep interval between the extensor carpi radialis longus (ECRL) and extensor carpi radialis brevis (ECRB) tendons.
- Then a 2-cm longitudinal incision along the dorsoradial aspect of the second metacarpal is made, taking care to retract and protect the extensor tendons and first dorsal interosseous muscle.
 - The second pin is placed through this incision.
- The external fixation frame is then slid into place over these initial two pins

and tightened.

- Using the open slots on the frame, the positions of the remaining two pins are marked, one in the metacarpal and one in the radial shaft.
- These pins are then inserted at these locations (**TECH FIG 4A**).

TECH FIG 3 • **A.** Fluoroscopy shows fracture reduction with K-wire pins in place. **B.** Pins in place through small wrist incisions.

TECH FIG 4 • A. External fixator pin placement. **B.** Final placement of external fixator. **C.** Postoperative radiograph. **D.** Testing DRUJ instability.

- The external fixator frame is then further tightened to stabilize the reduction (**TECH FIG 4B,C**).
- At this point, all fingers should have passive flexion and extension, and the wrist should not be placed in excessive flexion or ulnar deviation.
- The DRUJ is also assessed for stability (**TECH FIG 4D**).
 - With the elbow flexed at 90 degrees on the hand table, displacement in the dorsal-palmar direction is tested in neutral position, supination, pronation, and radial deviation. Radial deviation should stabilize the DRUJ unless there is a disruption of the triangular fibrocartilaginous complex (TFCC).
 - DRUJ instability is defined as more than 8 mm of ulnar translation relative to the radius in the dorsal-palmar direction.
 - If unstable, the distal ulna is reduced and pinned to the radius.

- If a large ulnar styloid fracture is noted, this can be fixed with a K-wire.

Completion and Closure

- Simple, interrupted 4-0 nylon sutures are used to close the skin incisions, taking care to avoid injuring the branches of the superficial radial nerve.
- Nonadherent dressings are applied to the pin sites.
- A thick layer of gauze is used to push the skin down from being tented on the pins.
- A volar splint is applied for additional support.

Postoperative Care

- The splint and dressings are removed 7 to 10 days postoperatively to evaluate the pin sites and skin incisions. Sutures are removed.
- Finger ROM is encouraged.
- Nonadherent dressings are applied to the pin sites for the first 3 weeks. If there is drainage, half-strength peroxide is used on a cotton-tipped applicator to clean the sites daily.
- If percutaneous K-wires were placed to stabilize the reduction, they can be removed in the office after 3 to 4 weeks while the external fixator is left in place.
- The patient can shower with the external fixator in place once all sutures and percutaneous K-wires are removed and incisions are dry.
- The external fixator is removed in the office after 4 to 6 weeks once the fracture has healed on clinical and radiographic examination.

■ Volar Plating

Equipment

- A tourniquet is used for this procedure.
- Bipolar cautery is useful for coagulating crossing vessels during exposure.
- A number of volar-locking plate systems exist. The surgeon must select a plating system and review the instruction manual thoroughly prior to use in the operating room. Particular attention must be paid to the distal locking screw trajectory for proper plate placement.
- The C-arm is required intraoperatively to assess fracture configuration and hardware placement throughout the procedure.

Pertinent Anatomy

- The surgical interval is between the flexor carpi radialis (FCR) tendon and the radial artery and brachioradialis (BR) tendon (see **FIG 3B**).
- The median nerve lies in the plane between the flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) muscle bellies in the forearm before emerging between FDS and flexor pollicis longus (FPL) more distally, entering the carpal tunnel at the wrist crease just deep to palmaris longus (PL).
- The palmar cutaneous branch of the median nerve arises 5 cm proximal to the wrist crease, between the PL and FCR. Notably, PL is absent in about 15% of the population.
- The FPL muscle overlies the pronator quadratus (PQ) and must be swept from radial to ulnar to expose PQ surgically.
- The PQ muscle is divided along its radial border and elevated to expose the bony surface of the distal radius and the associated fracture.
- The BR inserts into the distal radius and is often released during the procedure to decrease the deforming forces on the distal fragment, aiding fracture reduction.

Exposure

- The forearm is supinated on the hand table.
- A 6- to 8-cm incision is made at the radial aspect of the volar forearm between the FCR and the radial artery, ending just short of the wrist crease. If more distal exposure is required, the incision can be extended with a V-shaped zigzag (**TECH FIG 5A**).
- The FCR tendon sheath is entered, and the dissection proceeds along its radial aspect, to avoid the palmar cutaneous branch of the median nerve that is ulnar to the FCR, through the posterior sheath to expose the FPL muscle belly.
- The FPL is then swept ulnarly, exposing the PQ (**TECH FIG 5B**). The radial artery is also identified and retracted radially.
- An L-shaped incision is made through the PQ, releasing it radially and distally from the radius (**TECH FIG 5C**).
 - The PQ is elevated to expose the fracture site (**TECH FIG 5D**).
- The BR tendon can also be released at this point to further expose the distal fragment, which is usually displaced dorsally.

Fracture Reduction and Plate Fixation

- Next, fracture reduction is performed and may be provisionally held with K-wires.

TECH FIG 5 • **A.** Skin incision with FCR exposed. **B.** The PQ is exposed. **C.** The PQ is cut radially and distally in an L shape. **D.** The distal radius is exposed.

TECH FIG 6 • A. Volar plate placement. **B,C.** Intraoperative fluoroscopic images confirm appropriate plate placement.

- The volar plate is selected and placed centrally and distally on the radial shaft to capture the distal fragment.
- A screw is centrally placed through the elliptical plate hole into the radial shaft.
 - Although sizes can differ based on plating system, typically, a 2.0-mm drill bit is used, allowing for insertion of a 2.7-mm screw.
- Plate placement is then evaluated with C-arm fluoroscopy.

- By loosening the shaft screw, the plate can be shifted proximally or distally as needed.
- Once proper plate placement is achieved, the shaft screw is retightened. A second shaft screw is then inserted.
- With the wrist flexed, the distal screws are then placed, typically with a 1.8-mm drill bit and 2.4-mm screws.
- Locking screws can be used if the fracture is already properly reduced.
- However, if some separation exists between the distal fragment and the plate, a nonlocking screw can be placed initially to draw the bone to the plate.

TECH FIG 7 • A. The PQ is reattached, covering most of the plate. **B.** Skin closure.

TECH FIG 8 • A,B. AP and lateral postoperative

radiographs.

- Once the distal fragment is properly stabilized with a sufficient number of screws, the initial nonlocking screw can be exchanged for a locking screw, if desired (**TECH FIG 6A**).
- At this point, the provisional K-wires can be removed or left in place for 3 weeks if additional support is deemed necessary.
- Fluoroscopy is used to confirm appropriate plate placement (**TECH FIG 6B**).

Completion and Closure

- If the BR was released, it can be reattached with a step-cut lengthening maneuver.
- The PQ is then brought back over the plate and is sutured to the BR fascia using 3-0 Vicryl suture (**TECH FIG 7A**).
- The wound is closed with 3-0 Vicryl suture for the deep dermal layer, followed by a running subcuticular 3-0 Monocryl for the skin (**TECH FIG 7B**).
- A short-arm volar splint is placed for additional support, leaving the fingers free for ROM.

Postoperative Care

- Aggressive finger ROM is initiated immediately after surgery to decrease edema and avoid stiffness.
- The patient is evaluated in the clinic 10 to 14 days after surgery with repeat radiographs (**TECH FIG 8**), at which time gentle wrist ROM is initiated.

■ Dorsal Plate Fixation

Equipment

- A tourniquet is used for this procedure.
- A dorsal T- or L-shaped plate of an appropriate length must be selected. This plate is typically a 2.4-mm low-profile plate.
- A C-arm is used intraoperatively to evaluate fracture configuration and assess hardware placement.

Pertinent Anatomy

- The extensor retinaculum divides the extensor tendons into six dorsal compartments and serves to prevent tendon bowstringing (see **FIG 4A,B**).
- The ECRL/ECRB tendons lie in the second extensor compartment.
 - Care must be taken in this area to avoid injury to the radial sensory nerve and dorsal radial artery.
- The extensor pollicis longus (EPL) tendon lies in the third extensor compartment, passing in a groove ulnar to Lister tubercle.
 - It must be released and mobilized to expose the dorsal distal radius.
- The extensor indicis proprius (EIP) and extensor digitorum communis (EDC) tendons lie in the fourth extensor compartment.
 - They are elevated subperiosteally, thereby minimizing tendon contact with dorsally placed hardware.
 - The fourth extensor compartment also contains the terminal branch of the posterior interosseous nerve (PIN), which traverses the floor along its radial aspect and can be sacrificed without clinical import.
- The distal radius articulates with the scaphoid and lunate via two hyaline-covered concave facets.
- The two most important ligaments associated with the dorsal wrist capsule are the dorsal radiocarpal (DRC/radiotriquetral) and dorsal intercarpal (DIC/scaphotriquetral) ligaments (see **FIG 4C**).

Exposure

- A 6- to 8-cm longitudinal incision on the dorsal wrist is made in line with the third metacarpal, just ulnar to Lister tubercle between the third and fourth extensor compartments (**TECH FIG 9**).

TECH FIG 9 • Planned incision on wrist.

- Care is taken to preserve the branches of the superficial radial nerve.
- Full-thickness flaps are raised to expose the extensor retinaculum.
- The third compartment is longitudinally incised, exposing the EPL tendon.
- The EPL tendon is released from its groove, and the retinaculum is divided between the septa of the third and fourth compartments.
- A periosteal elevator is used to elevate the fourth compartment in the subperiosteal plane to expose the bony surface.
- A longitudinal capsulotomy may be required to expose the articular surface, which is performed by releasing the dorsal capsular insertions from the distal nonarticular lunate.
- Once the fracture site and articular surface are exposed, Lister tubercle should be removed with a rongeur to allow the plate to sit flush on the dorsal cortex.

Fracture Reduction and Plate Fixation

- Fracture reduction is then accomplished with provisional K-wire fixation.
- A T-shaped plate is selected and contoured.
- Fluoroscopy is used to adjust the position of the plate proximally or distally as needed.
- Articular congruity is confirmed with fluoroscopy.
- The screws are applied sequentially to finalize plate (**TECH FIG 10**).
- Once the fracture is stabilized, the DRUJ is assessed for instability.

- If deemed unstable, the DRUJ should be pinned percutaneously with the forearm in supination.

Completion and Closure

- The dorsal capsule and extensor retinaculum are closed with 3-0 and 2-0 nonabsorbable suture, respectively.
- The EPL tendon should remain in its new position superficial to the retinaculum.
- The skin is closed with simple interrupted 3-0 nylon suture.
- A volar splint leaving the thumb and fingers free is applied for postoperative comfort.

Postoperative Care

- The splint is removed at the first postoperative visit in 7 to 10 days, and active and passive finger ROM exercises are initiated.
- A removable short-arm volar splint is applied in neutral position, to be removed 5 to 7 times daily for wrist ROM exercises.
- A compression garment is applied for postoperative edema control.
- The splint can be weaned at 4 weeks to allow for activities of daily living.
- Once fracture healing has completed at about 6 to 8 weeks (**TECH FIG 11**), the splint is permanently discontinued.
 - However, if DRUJ instability was addressed in the procedure, the postoperative immobilization period is extended.

TECH FIG 10 • **A.** In situ plate placement. **B–D.** AP, lateral, and close-up lateral fluoroscopic views, respectively, showing final plate placement.

TECH FIG 11 • A–C. AP, oblique, and lateral postoperative radiographs.

■ Dorsal Bridge Plate Fixation

Equipment

- A tourniquet is used for this procedure.
- A distal radius bridge plate of an appropriate length must be selected. This plate is typically a 2.4-mm combination plate with smooth, beveled edges.
 - If such a plate is not available, a 2.7- or 3.5-mm limited contact dynamic compression plate (LC-DCP) can be used.
- A C-arm is used intraoperatively to help plan surgical incisions, evaluate fracture configuration, and assess hardware placement.

Pertinent Anatomy

- Dorsal bridge plate fixation is designated for highly comminuted, intra-articular distal radius fracture (**TECH FIG 12**).
- When placed, the bridge plate passes superficial to the joint capsule and periosteum within the second extensor compartment.

- The extensor tendons overlying the index finger metacarpal must be retracted to facilitate distal fixation of the bridge plate.
- The proximal portion of the bridge plate is placed along the dorsoradial aspect of the radial shaft, adjacent to the BR.

Site Preparation and Exposure

- Fluoroscopy is used to mark the location of the proximal extent of the plate over the radial shaft, which should allow the placement of three screws at least 4 cm proximal to the fracture site.
 - The distal end of the plate should overlie the third or second metacarpal, no farther than the metacarpal neck.
 - These landmarks should guide incision placement.
- Two or three small longitudinal incisions are made dorsally to facilitate exposure (**TECH FIG 13A**).
 - A 4-cm incision is made over the dorsal midshaft of the index finger metacarpal. The extensor tendons are identified and retracted (**TECH FIG 13B**).
 - A second 4- to 6-cm incision is made dorsoradially overlying the radial shaft, just proximal to the EPB and APL muscles. The ECRL and ECRB tendons are identified and the radial shaft is exposed, allowing for placement of three screws at least 3 to 4 cm proximal to the fracture.

TECH FIG 12 • A,B. PA and lateral radiographs showing comminuted intra-articular distal radius fracture.

- A third separate 3-cm incision over Lister tubercle may also be made if an articular reduction or metaphyseal bone grafting is needed. The EPL tendon is mobilized to facilitate exposure and reduction.

Placement of the Plate

- Metzenbaum scissors are inserted, proximal to distal, along the floor of the second extensor compartment to create a tunnel, ensuring that the periosteum and joint capsule remain deep to the tunnel.
- The plate is then passed from the distal incision to the proximal incision (**TECH FIG 14A**), staying deep to the index finger extensor tendons.
- Manual traction of the wrist is used to obtain provisional reduction of the fracture, restoring radial length and inclination.
- Under fluoroscopy, the plate is aligned centrally over the index metacarpal and radial shaft.
- A bicortical screw is placed in the penultimate hole at the midline of the

metacarpal shaft.

- While traction is reapplied under fluoroscopy to confirm fracture and plate alignment, the proximal end of the plate is clamped to the radial shaft using serrated bone-holding clamps.

TECH FIG 13 • **A.** Planned incisions. **B.** Incision over index finger metacarpal.

TECH FIG 14 • A. Dorsal plate placement. Intraoperative fluoroscopic images showing fixation at the second metacarpal (**B**) and at the radial shaft (**C**).

- Fluoroscopy and clinical assessment are necessary to ensure restoration of radial length, radial inclination, and volar tilt, as well as absence of rotational abnormalities.
- Supination and pronation of the forearm should be assessed to confirm full ROM.
- When plate position is deemed appropriate, three bicortical screws are placed proximally in the radial shaft, securing the plate.

- Two additional bicortical screws are applied to the metacarpal, for a total of three distal points of fixation.
- Fluoroscopy is used to check plate placement (**TECH FIG 14B,C**).

Additional Fracture Reduction and Fixation

- Once the dorsal bridge plate is in place, any diaphyseal fragments amenable to lag screw fixation can be fixated to the radial shaft.
- If any further reduction of the articular surface is required, the third incision (explained above) can be used to release the EPL tendon and pass the plate.
- A dental pick can be used to reduce the articular incongruity.
- If possible, a 2.7-mm cortical screw is inserted through the plate directly under the lunate fossa as a buttress against subchondral collapse.
- Grafting with bone or allograft can also be performed to achieve subchondral and metaphyseal support of the articular reduction.
- K-wires (0.045 or 0.062 in.) can also be placed percutaneously to hold small articular fragments in reduction.

Completion and Closure

- Incisions are typically closed with 3-0 Vicryl sutures for the deep dermal layer, followed by a subcuticular running 3-0 Monocryl for the skin.
- A bulky dressing and volar wrist splint are applied for additional support, leaving fingers free for immediate active and passive ROM exercises.

Postoperative Care

- Active and passive digital ROM exercises are encouraged throughout the healing process.
- The first postoperative visit with radiographic films is at 7 to 10 days (**TECH FIG 15**), at which time a compression garment is applied to control edema, and a thermoplastic short-arm splint is provided.
- If K-wires were placed, they can be removed at 6 weeks.
- Patients may use the operated extremity for activities of daily living.
- Finger ROM, pronation, and supination are encouraged.
- Patients should not lift more than 5 lb. As long as restrictions are maintained, patients may return to work.
- Hardware removal can be scheduled at about 8 to 12 weeks after surgery, once bony healing has been achieved.
- Finger and wrist ROM exercises are initiated immediately after plate

removal.

TECH FIG 15 • **A,B.** PA and lateral postoperative radiographs of dorsal bridge plate in place.

PEARLS AND PITFALLS

PERCUTANEOUS PINNING

General K-wire technique

- Avoid multiple K-wire passes to prevent further fragmentation of fracture pieces, particularly in osteopenic bone.

Percutaneous pinning technique

- For pin placement, the authors prefer using a small longitudinal incision over the radial styloid to avoid skewering branches of the superficial radial sensory nerve and the extensor tendons.
- If the pins are placed percutaneously, caution is advised, as nerves and tendons can be easily damaged.

Adjunctive external

- Consider concomitant external fixation in patients greater than 55 y of age and in younger patients if both the dorsal and volar

fixation	cortices are comminuted.
Over-reduction	■ Avoid over-reducing the fracture fragment, as excessive volar flexion can displace the fragment volarly.
Pediatric distal radius fractures	■ Often, pediatric fractures can be reduced and stabilized with a single K-wire.

EXTERNAL FIXATION

Alignment of external fixator	■ The external fixator should be aligned at about 45 degrees dorsally from the radial midlateral axis. ■ This dorsoradial position for external fixator placement should allow for full thumb ROM, particularly thumb retropulsion, with the fixator in place. ■ Postoperative radiographs can also be obtained without obstruction by the fixator in this position.
General pin placement	■ Pins should be bicortical and stable prior to external fixator frame placement. ■ If the bone is weak and osteopenic, the proximal metacarpal pin may be placed through the second metacarpal base into the third metacarpal base for further stability. However, if the metacarpal pins are placed too deep, the motor branch of the ulnar nerve may be injured. ■ When the proximal pins are placed between the ECRL and ECRB tendons into the radial shaft, the ECRL tendon acts as a protective barrier between the superficial radial nerve and the pins.
Percutaneous approach	■ If the external fixator pins are placed percutaneously, whether in the radial shaft or in the second metacarpal, the superficial radial nerve can inadvertently be injured. ■ The authors prefer using small incisions for direct visualization and protection of the nerve branches.
External fixator frame placement	■ Avoid overdistractive of the frame, as this may lead to wrist stiffness or limited finger ROM. ■ If the external fixator is placed in excessive flexion and ulnar deviation, carpal tunnel symptoms may occur. ■ External fixators can be used to supplement the fixation of highly comminuted distal radius fractures with percutaneous pins or internal plating. External fixation serves to off-load the carpus during the healing process.

VOLAR PLATING

Exposure	■ Avoid soft tissue stripping too far distally on the radius, as inadvertent release of the volar carpal ligaments will result in carpal instability. ■ Mobilizing the radial artery and ligating its ulnar-crossing branches will help to minimize bleeding and permit better exposure of the BR for release. ■ Avoid dissection ulnar to the FCR tendon, as the palmar cutaneous branch of the median nerve can be injured.
Release of the BR tendon	■ Not always necessary ■ Can be useful in fracture reduction ■ Dissection must proceed entirely on bone to avoid damage to the tendons of the first extensor compartment. ■ At the end of the procedure, the BR can be reattached using a step-cut lengthening maneuver.
Fracture reduction	■ A Freer elevator can be used to lever the distal fragment into place. It must be inserted through the fracture site into the dorsal cortex for complete disimpaction of the distal fragment to permit proper reduction. ■ Flexing the hand and wrist can promote reduction. ■ A large towel bump under the hand and distal fragment may be useful in the reduction maneuver. ■ Avoid over-reduction of the fracture, which can lead to volar displacement.
Intraoperative imaging	■ The C-arm is used to assess plate and screw placement. ■ The AP view confirms proper radioulnar placement of the plate. ■ The lateral view confirms proper proximal-distal placement of the plate. ■ A fossa lateral view, which is taken by holding the forearm at 22 degrees from the plane of the hand table, allows visualization of the radiocarpal joint space to ensure no screw penetration.
Screw placement	■ Avoid placing screws that are too long, as they may cause attritional extensor tendon rupture. The distal locking pegs or screws must be about 2 mm short of reaching the dorsal cortex. ■ Avoid screw penetration into the radiocarpal joint and DRUJ. ■ The distal screws are designed for subchondral support (distal row) and for dorsal fixation (proximal row) of the distal fragment.
Reattachment	■ Often cannot be fully reattached due to plate prominence

of the PQ	■ Partial closure allows for some soft tissue coverage of the plate. ■ Avoid inadvertent suturing of the first extensor compartment tendons. ■ Some surgeons do not suture the PQ back into place at all.
------------------	---

Volar plate removal	■ Approximately 15%–20% of volar plates are eventually removed. ■ Reasons for removal of hardware included tenosynovitis, tendon rupture, pain, and prominent or intra-articular hardware.
----------------------------	---

DORSAL PLATING

Exposure	■ Full-thickness flaps are elevated, including skin, subcutaneous tissue, and superficial fascia. These flaps will contain and protect the dorsal sensory branches of the ulnar and radial nerves. ■ Elevating the fourth compartment in the subperiosteal plane minimizes plate contact with the extensor tendons. ■ Small incisions for provisional K-wire placement in the area of the radial sensory nerve are recommended to avoid damaging the nerve branches.
-----------------	--

Dorsal capsulotomy	■ Can be performed to address fractures involving the articular surface. ■ Involves a longitudinal incision that detaches the dorsal capsular insertions from the distal nonarticular lunate. ■ The intercarpal ligaments must be protected. ■ Avoid entering the DRUJ. Radioulnar instability can result if the dorsal radioulnar ligament is divided.
---------------------------	--

Lister tubercle	■ The EPL tendon passes in a groove just ulnar to the Lister tubercle. ■ Lister tubercle is removed with rongeurs such that the plate can sit flush with the dorsal cortex and be less prominent.
------------------------	--

Bone grafting	■ Cancellous bone grafting of metaphyseal defects can help support an articular reduction.
----------------------	--

Screw placement	■ Avoid placing screws that are too long, as this can lead to irritation of volar structures.
------------------------	---

DORSAL BRIDGE PLATE FIXATION

Incisions	■ Fluoroscopy is used to guide placement of incisions. ■ By holding the distal end of the plate at the index metacarpal neck-shaft junction, the proximal extent of the plate can be marked over the radial shaft. One must ensure that 3 screws can be placed at least 3 to 4 cm proximal to the fracture.
------------------	--

	■ A third incision over the Lister tubercle can be made for articular reduction and metaphyseal bone grafting, if necessary.
Dorsal bridge plate placement	■ The plate is placed along the floor of the second extensor compartment, deep to the index finger extensors and wrist extensors and superficial to the periosteum. ■ The plate should not extend distal to the index metacarpal neck. ■ The distal screw must be in the midline of the index metacarpal shaft to avoid rotary displacement of the fracture. ■ Applying traction with the forearm in 45–60 degrees of supination before applying the serrated clamp is helpful to avoid pronation of the distal fragment.
Overdistraktion	■ Defined as a radiocarpal gap greater than 5 mm. ■ Can lead to loss of finger ROM secondary to extrinsic extensor tightness ■ Can lead to development of complex regional pain syndrome (CPRS).
Articular reduction and bone grafting	■ Failure to reduce articular fragments can lead to symptomatic radiocarpal arthrosis. ■ If an articular reduction is performed, bone grafting provides subchondral and metaphyseal support of the reduction. ■ Contraindications to bone grafting: ■ Open fractures with gross contamination ■ Soft tissue defects precluding primary wound closure
DRUJ instability	■ Defined as greater than 8 mm of palmar to dorsal translation of the ulna relative to the radius ■ Should be suspected in cases with large ulnar styloid fractures or displaced ulnar head fractures ■ After bridge plate placement, the DRUJ should be assessed for instability. ■ If DRUJ instability is detected, the forearm should be immobilized in supination for 3–4 wk.
Bridge plate removal	■ Plate removal can be electively scheduled at 8–12 wk after the initial surgery. ■ The plate should stay in place until radiographic osseous healing has occurred. Bridging callous should be seen in both the sagittal and coronal planes. ■ Bony healing may be difficult to visualize with a thick 3.5-mm plate in place. ■ Early removal of the plate can lead to fracture collapse. ■ Late removal of the plate may lead to extensor tendon attrition

and rupture or permanent wrist stiffness.

OUTCOMES

- Excellent long-term outcomes have been reported for all techniques when used in the appropriate patients.¹ Indeed, patient selection is critical.
 - Over the past decade, however, internal fixation has become increasingly popular due to perceived early functional benefits.
- Of the internal fixation options, volar plates are favored over dorsal plates due to fewer tendon-related complications.
- With regard to external vs internal fixation, studies have shown no significant differences in grip strength, wrist ROM, radiographic alignment, and pain.
- Still, the existing literature is heterogeneous with respect to reported outcomes for the treatment of distal radius fractures. As such, a unified approach has been recently proposed to integrate performance, patient-reported outcomes, pain, complications, and radiographs.²
- For the elderly population, management of distal radius fractures has traditionally been dominated by closed reduction and immobilization.
 - Nonoperative management was found to achieve satisfactory functional outcomes despite the presence of fracture malalignment.
 - However, today's elderly population is more active than prior generations, which may indicate the need for more accurate fracture fixation for maintaining function. A multicenter prospective study to further investigate outcomes in this population is currently under way.

COMPLICATIONS

- The overall complication rate after fixation of distal radius fractures has been reported to be as high as 30%.³
- Pin-track or superficial infections associated with external fixation are the most common type of postoperative infection following distal radius fixation, with an overall incidence of 25%.
 - *Staphylococcus aureus* is the most commonly isolated microbe.
 - Nearly all reported infections resolve with oral antibiotics, with or without pin removal.
- Internal fixation of distal radius fractures, whether volar or dorsal, has lower infection rates, only up to 3%.
- Open fractures of the distal radius, regardless of fixation method, are

associated with a higher rate of infection of 44%.

- Clinically relevant extensor tendon injury or rupture is uncommon for both percutaneous pinning and external fixation, less than 1%. The use of small incisions to facilitate direct visualization and protection of important structures during pin placement is generally advocated.
- EPL rupture is, however, a well-documented complication of volar plating, with an incidence of 2% to 9%. It is typically caused by drill bit penetration or prominent dorsal screw tips. EPL rupture can also occur with nonoperative treatment. It is believed that the EPL near the Lister tubercle has poor intrinsic vascularity, and when combined with nutritional interference from hematoma, delayed EPL rupture ensues. Should EPL rupture occur, reconstruction can be performed with tendon grafting or an EIP tendon transfer.
- Extensor tenosynovitis may also occur with prominent dorsal screw tips from volar plating, with an incidence of up to 14%. This is addressed with hardware removal. In particular, dorsal plating is associated with an unacceptably high rate of extensor tendon complications, ranging from 19% to 48%. The advent of ultra-low profile plates appears to have decreased the incidence of such complications.
- Flexor tendon injury is less common than extensor tendon injury following fixation of distal radius fractures and is mostly associated with volar plating.
 - The FPL is the most frequently ruptured flexor tendon.
 - Flexor tenosynovitis may occur and may be treated with implant removal.
 - Some surgeons advocate repair of the PQ as a protective layer between volar hardware and flexor tendons.
- Carpal tunnel syndrome, or median neuropathy, can occur acutely, subacutely, or in a delayed fashion after distal radius fractures regardless of treatment method, operative or nonoperative, with an overall incidence of 8.5%.
 - Some surgeons advocate carpal tunnel release in all distal radius fractures undergoing fixation, whereas others limit this to patients with pre-existing or acute signs of median neuropathy.
- Superficial radial nerve (SRN) injury is most common with percutaneous pinning and external fixation, with an incidence of 4% to 13%. Using small skin incisions to facilitate direct visualization and preservation of the nerve branches during pin placement reduces this risk.
- Complex regional pain syndrome has been associated with distal radius fractures treated both operatively and nonoperatively, with rates ranging from

3% to 25%.

- It is characterized by unexplained pain, swelling, vasomotor instability, and joint stiffness.
- Type I (previously known as reflex sympathetic dystrophy) occurs secondary to a noxious event. Type II (also known as causalgia) is caused by direct peripheral nerve injury.
- The use of vitamin C for CPRS prophylaxis is controversial, but many still advocate it given its low side effect profile.
- Loss of reduction can occur following all forms of distal radius fixation and is most commonly seen with percutaneous pinning, followed by external fixation and subsequently internal plating.
- Internal fixation with plates seems to maintain radiographic parameters better than other fixation methods.
- Reoperation is performed in up to 80% of cases in which loss of reduction is discovered.
- In particular, lunate facet fractures are prone to loss of reduction.
- Some surgeons advocate other fixation methods as an adjunct to plating, such as pins, wires, sutures, or mini-screws.
- Nonunion after distal radius fixation is rare, with an incidence of less than 1%.
 - If nonunion is experienced, revision is indicated with plate fixation and autogenous bone grafting.
- Approximately 65% of patients with intra-articular distal radius fractures go on to develop radiographic evidence of radiocarpal arthritis, regardless of treatment modality.
 - Radiographic evidence of radiocarpal arthritis does not seem to correlate with patient symptoms or functional impairment, however, and functional outcomes seem to be no different from population norms.

Section VI: Rheumatoid Arthritis

24 Rheumatoid Arthritis of the Hand and Wrist

CHAPTER

Shoshana W. Ambani and Kevin C. Chung

DEFINITION

- Rheumatoid arthritis (RA) is a systemic autoimmune disease characterized by synovial inflammation, which results in progressive joint and soft tissue destruction that leads to deformity and disability.

PATHOGENESIS

- RA is an idiopathic disease affecting about 0.5% to 1.0% of the adult population, with both genetic and environmental factors, which are not fully understood.
- For example, there is a three- to fourfold higher frequency in women compared to men. In addition, patients with the human leukocyte antigen-antigen D related (HLA-DR) allele have a 4 to 5 increased relative risk of RA.¹
- Environmental links have also been made, particularly to smoking, caffeine, silica, and some infectious diseases.
- On a cellular level, autoreactive T cells and inflammatory cytokines have been found to play a critical role in the pathogenesis of RA.^{2,3}
- Tumor necrosis factor (TNF) and interleukin-6 (IL-6), for example, promote inflammatory cell accumulation, production of matrix metalloproteinases, and osteoclast activation, which ultimately results in the destruction of cartilage and bone.

DIAGNOSIS

- The diagnosis of RA is clinical, based on criteria developed by the American College of Rheumatology (ACR, previously the American Rheumatism Association) in 1987 to distinguish RA from other rheumatic diseases (Table 1).⁴
- In general, the diagnosis is made by recognizing a pattern of sign and symptoms, including a history of prolonged morning stiffness that may improve with activity, polyarthralgias, joint swelling, and fatigue.
- Blood work can help exclude the mimics of RA.
 - Anti-cyclic citrullinated peptide (anti-CCP) antibodies have been shown to be more than 90% specific for RA.³⁻⁵
 - Rheumatoid factor (RF), though not necessary to confirm the diagnosis of RA, is associated with more severe joint disease and extra-articular manifestations.
- Examination findings suggestive of RA include symmetrical polyarthritis and rheumatoid nodules.
- Arthrocentesis may be helpful in excluding septic arthritis.
- Radiographs may be obtained, revealing periarticular osteopenia, joint space loss, and erosions.
- In 2010, the ACR/European League Against Rheumatism (EULAR) developed further criteria for diagnosis in an effort to help identify patients who would benefit from disease-modifying antirheumatic drugs (DMARDs) early on before the irreversible effects of RA take place (Table 2).⁶

DIFFERENTIAL DIAGNOSIS

- Viral polyarthritis
- Systemic rheumatic diseases (eg, systemic lupus erythematosus, Sjogren syndrome, dermatomyositis, mixed connective tissue disease)
- Palindromic rheumatism
- Hypermobility syndrome and fibromyalgia
- Reactive arthritis and arthritis of inflammatory bowel disease
- Psoriatic arthritis

Table 1 1987 ACR Criteria for Rheumatoid Arthritis^a

1. Morning stiffness
 - Located in and around joints

• Duration ≥ 1 h before maximal improvement
2. Arthritis of ≥ 3 joint areas • At least 3 joints simultaneously have had soft tissue swelling or fluid, witnessed by a physician • May involve 4 possible joints: PIP, MCP, wrist, elbow, knee, ankle, and MTP joints
3. Arthritis of hand joints • At least 1 area with soft tissue swelling or fluid (wrist, MCP, or PIP joint)
4. Symmetrical arthritis • Simultaneous involvement of same joints on both sides of body • Bilateral involvement of PIPs, MCPs, or MTPs, without absolute symmetry, is acceptable
5. Rheumatoid nodules • Subcutaneous nodules over bony prominences, extensor surfaces, or in juxta-articular regions, observed by a physician
6. Serum rheumatoid factor • Demonstration of abnormal amounts of serum rheumatoid factor by any method for which the result has been positive in less than 5% of normal control subjects
7. Radiographic changes • Includes erosions or unequivocal bony decalcification localized to the involved joints • Osteoarthritic changes alone do not qualify

PIP, proximal interphalangeal; MCP, metacarpophalangeal; MTP, metatarsophalangeal.

^aA patient is diagnosed with rheumatoid arthritis if at least 4 of the 7 criteria are met. Criteria 1 to 4 must have been present for at least 6 weeks.

From Arnett FC, Edworthy SM, Bloch DA, et al. The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis. *Arthritis Rheum.* 1988;31(3):315-324.

Table 2 2010 ACR/EULAR Classification Criteria for Rheumatoid Arthritis

Classification Criteria	Score
• Add scores of categories A–D. • A score of $\geq 6/10$ is required for diagnosis of RA.	
A. Joint involvement (any swollen or tender joint on examination, excluding DIPJ, first CMCJ, and 1st MTPJ)	

• 1 large joint	0
• 2–10 large joints	1
• 1–3 small joints (with or without large joint involvement)	2
• 4–10 small joints (with or without large joint involvement)	3
• Greater than 10 joints	5
Note: “Large” joints refer to shoulders, elbows, hips, knees, and ankles; “small” joints refer to MCPJ, PIPJ, 2nd–5th MTPJ, thumb IPJ, and wrists.	
B. Serology (at least 1 test result is needed for classification)	
• Negative RF <i>and</i> negative ACPA	0
• Low-positive RF <i>or</i> high-positive ACPA	2
• High-positive RF <i>or</i> high-positive ACPA	3
C. Acute-phase reactants (at least 1 result is needed for classification)	
• Normal CRP <i>and</i> normal ESR	0
• Abnormal CRP <i>or</i> abnormal ESR	1
D. Duration of symptoms	
• <6 weeks	0
• ≥6 weeks	1

CMCJ, carpometacarpal joint; DIPJ, distal interphalangeal joint; IPJ, interphalangeal joint; MCPJ, metacarpophalangeal joint; MTPJ, metatarsophalangeal joint; RF, rheumatoid factor; ACPA, anti-citrullinated protein antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

From Aletaha D, Neogi T, Silman AJ, et al. 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative. *Arthritis Rheum.* 2010;62(9):2569-2581.

- Polymyalgia rheumatic
- Crystalline arthritis (eg, gout, pseudogout)
- Infectious arthritis

- Osteoarthritis
- Paraneoplastic disease
- Multicentric reticulohistiocytosis
- Sarcoid arthropathy
- Fibroblastic rheumatism

IMAGING

- When evaluating the upper extremities, PA, oblique, and lateral radiographs of the hands should be obtained to assess the condition of the proximal interphalangeal joints (PIPJ) and metacarpophalangeal joints (MCPJ).
- Radiographs of the wrist will further serve to evaluate the distal radioulnar joint (DRUJ), midcarpal joint, and radiocarpal joint.
- Characteristic findings of RA include periarticular osteopenia, joint space loss, and marginal joint erosions (**FIG 1**). Often, these changes are not seen in early disease.
- MRI can be useful in detecting RA before radiographic changes can be detected. MRI can also identify bone marrow edema and synovial hypertrophy, which predict the development of erosive disease.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically present between the third and sixth decades of life. Symptoms begin insidiously and grow over weeks to months. Patients complain of fatigue, malaise, generalized stiffness, and generalized arthralgias or myalgias.
 - In a small subset (10%–15%) of patients, the onset of RA is sudden, with fever, polyarthritis, lymphadenopathy, and splenomegaly developing over days to weeks.
- Inflammation of the synovial tissues (synovitis) develops gradually and often symmetrically in the hands, wrists, knees, and feet. Synovial hypertrophy (pannus) ultimately results in the destruction of ligaments, tendons, cartilage, and bone. Examination of affected joints reveals swelling, tenderness, warmth, and painful motion.
 - In the upper extremity, RA tends to affect the MCPJ, PIPJ, and wrists earlier and more frequently than it does other joints in the body. This is in part due to their high synovium-to-joint surface area ratio.
 - The distal interphalangeal joints (DIPJ) are typically spared from RA.

FIG 1 • Radiographs of rheumatoid hand and wrist showing periarticular osteopenia, joint space loss, and marginal joint erosions. **A.** AP view. **B.** Oblique view. **C.** Lateral view.

FIG 2 • Rheumatoid nodule on elbow.

- Patients may also present with rheumatoid nodules, vasculitis, pericarditis, pleural effusion, interstitial pulmonary disease, peripheral neuropathy, and

keratoconjunctivitis sicca.

- Rheumatoid nodules tend to develop on extensor surfaces or areas of contact pressure, such as the olecranon process at the elbow (**FIG 2**).
- RA also affects the synovial lining of tendons, which can result in carpal tunnel syndrome, tendon rupture, tendonitis, and trigger digits.

Key Findings

- Wrist (carpus)
 - Midcarpal extension
 - Ulnar translocation of the carpus
 - DRUJ instability
 - Caput ulna (ulnar head dorsal dislocation, ECU subluxation, carpal supination)
 - Extensor tendon rupture, Vaughn-Jackson syndrome
 - Flexor pollicis longus (FPL) rupture (Mannerfelt lesion)
 - Carpal tunnel syndrome
- Hand
 - MCPJ and PIPJ arthritic changes
 - MCPJ volar subluxation and ulnar deviation
 - Sparing of the DIPJ
 - Swan-neck deformity
 - Boutonniere deformity

Wrist Joint

- Arthritic radiographic changes are initially noted at the scaphoid waist, the ulnar styloid, and the DRUJ and progress into the radiocarpal and midcarpal joints.
 - In later stages, severe erosion of the volar lip of the distal radius leads to lunate malposition (proximal migration, volar translation, volar angulation) and compensatory midcarpal extension.
- Three patterns of end-stage carpal arthritis can be encountered, depending on the degree of bony destruction and ligamentous instability.
 - First, wrist ankylosis (bony joint fusion) can occur, sometimes in acceptable alignment.
 - Second, the wrist can be arthritic but stable over time with limited ligamentous destruction.
 - Third, the wrist is unstable, characterized by progressive misalignment,

whether ligamentous or bony in etiology.

Carpal Ligaments

- Normal carpal ligament anatomy is shown in **FIG 3A,B**.
- In RA, synovitis attenuates the radioscaphocapitate (RCC) ligament and the scapholunate (SL) ligament, causing ulnar translocation of the carpus.
- At the DRUJ, the triangular fibrocartilage complex (TFCC), including the dorsal and palmar radioulnar ligaments, is also destroyed by synovitis, leading to DRUJ instability and eventual dorsal dislocation of the ulnar head. The extensor carpi ulnaris (ECU) sheath is also destroyed, resulting in volar ECU subluxation and contributing to the supinated and radially deviated posture of the wrist (**FIG 3C**).
- The term *caput ulna* refers to the combination of dorsal ulnar head dislocation, volar ECU subluxation, and carpal supination (**FIG 3D,E**).

Tendons at the Wrist

- Synovitis develops within the extensor tendon compartments on the dorsal aspect of the wrist (**FIG 4**).

FIG 3 • Palmer (A) and dorsal (B) views of normal anatomy of carpal ligaments and TFCC. C. Wrist changes in RA. D,E. Caput ulna of the right hand.

- Pannus can be seen bulging proximally and distally from underneath the extensor retinaculum, taking on an hourglass appearance.
- Tendon rupture in RA results from direct pannus invasion and/or attritional wear over eroded bony edges.
- In regions where the tendon is covered by tenosynovium (eg, extensor retinaculum, carpal tunnel, and digital flexor sheaths), tendons may be directly invaded by synovial pannus.
- In regions where tendon is closely related to joints (eg, the DRUJ, radiocarpal joint, and PIP joints), underlying proliferative synovitis may cause pressure ischemia leading to tendon rupture.

- Attritional rupture frequently involves the extensor digiti minimi (EDM) at the ulnar head, the extensor pollicis longus (EPL) at the Lister tubercle, and the FPL in the carpal tunnel, which is caused by a flexed, eroded scaphoid. An attritional FPL rupture is termed a *Mannerfelt lesion*.

FIG 4 • Extensor tendons of the hand and wrist.

Table 3 Examining the Tendons of the Hand

Tendon	Examination Maneuver	Interpretation and Pearls
Extensor pollicis longus (EPL)	• With the patient's palm flat on a table, ask the patient to lift the thumb off the table.	If able to lift the thumb off the table (retropulsion), EPL is intact.
Extensor indicis proprius (EIP)	• Test independent extension of the index finger with the remaining fingers held in flexion.	It is important to test the integrity of EIP, as it is a common donor in tendon transfer procedures.
Extensor digitorum communis	• With the finger passively placed in extension, ask the patient to maintain the finger	• One must differentiate extensor tendon rupture from (1) ulnar subluxation of the

(EDC)	in extension. If unable to maintain finger extension, there is either a tendon rupture or nerve palsy. • Next, test the <i>tendodesis effect</i> by passively flexing the patient's wrist and looking for concomitant finger extension. If the finger does not extend, tendon rupture is the diagnosis, as the tenodesis effect is preserved in nerve palsy.	extensor tendon over the head of the metacarpal and (2) posterior interosseous nerve (PIN) palsy secondary to elbow synovitis. • Patients with rupture of the EDC to one finger may still be able to extend that finger due to the juncturae connecting it to the adjacent fingers. • Usually, the finger cannot be extended if more than one EDC is ruptured.
Extensor digiti minimi (EDM)	Test independent extension of the small finger with the other fingers flexed.	• Patients may still be able to extend the small finger while extending the remaining fingers through an intact EDC or the juncturae connecting it to the ring finger.
Flexor pollicis longus (FPL)	Holding the thumb MCPJ in extension, ask the patient to flex the thumb IP joint.	• Intact thumb IP flexion indicates an intact FPL tendon.
Flexor digitorum superficialis (FDS)	FDS is checked for each finger by holding the patient's other fingers in extension and allowing the patient to actively flex the finger in question.	• If FDS is intact, the finger will bend at the PIPJ. • It is important to test the integrity of FDS to the ring and long fingers, as they are commonly used in tendon transfer procedures.
Flexor digitorum profundus (FDP)	FDP is checked for each finger by holding the PIPJ straight and asking the patient to flex the DIPJ.	• If FDP is intact, the finger will bend at the DIPJ.

- The most frequently ruptured tendons are the EDM, followed by the extensor digitorum communis (EDC) tendons of the small, ring, long, and index fingers; the EPL; the FPL; and, least commonly, the flexor digitorum superficialis

(FDS) and profundus (FDP) tendons.

- Extensor tendon ruptures often progress from ulnar to radial, eventually affecting all digits, referred to as *Vaughn-Jackson syndrome*. Tendon ruptures occur suddenly, may not be painful, and must be differentiated from volar subluxation of the MCPJ, radial nerve palsy, and extensor tendon subluxation at the MCPJ. Flexor tendon ruptures occur less often.
- A thorough tendon examination (Table 3) is warranted to determine reconstructive options after tendon rupture (Table 4).

Table 4 Tendon Transfer Options for Rheumatoid Attritional Ruptures

Physical Findings	Ruptured Tendon(s)	Reconstructive Options
Lack of small finger extension	• EDM at ulnar head	• End-to-side repair of EDM to ring finger EDC
Lack of small and ring finger extension	• EDM at ulnar head • EDC to small finger • EDC to ring finger	• EIP transfer to EDM and ring finger EDC
Lack of small, ring, and long finger extension	• EDM at ulnar head • EDC to small finger • EDC to ring finger • EDC to long finger	• EIP transfer to EDM and ring finger EDC • End-to-side repair of long finger EDC to index finger EDC
Lack of small, ring, long, and index finger extension	• EDM at ulnar head • EDC to small finger • EDC to ring finger • EDC to long finger • EDC to index	• Long finger FDS to index and long finger EDC • Ring finger FDS to ring finger EDC and small finger EDC/EDM (whichever tendon is more robust)

	- finger • EIP	
Lack of thumb extension (retropulsion)	• EPL at Lister tubercle	• Preferred: EIP transfer to EPL • Alternatives: ◦ ECRL to EPL ◦ EDM to EPL
Lack of thumb, index, long, ring, and small finger extension	• EDM at ulnar head • EDC to small finger • EDC to ring finger • EDC to long finger • EDC to index finger • EIP • EPL at Lister tubercle	• Long finger FDS transfer to EPL and index finger EDC • Ring finger FDS transfer to long and ring finger EDC and small finger EDC/EDM (whichever tendon is more robust)
Lack of thumb IPJ flexion	• FPL in carpal tunnel	• Preferred: BR transfer to FPL • Alternatives: ◦ ECRL transfer to FPL ◦ Long finger FDS transfer to FPL ◦ Thumb IPJ fusion
Lack of independent PIPJ flexion (of any finger)	• FDS (any finger)	• PIPJ synovectomy (to prevent FDP rupture)
Lack of DIPJ flexion (of any finger)	• FDP (any finger)	• Preferred: DIPJ arthrodesis • Alternative: DIPJ tenodesis
Inability to flex PIPJ and DIPJ (of any finger)	• FDS and FDP (any finger)	• Staged flexor tendon reconstruction

BR, brachioradialis; DIPJ, distal interphalangeal joint; ECRL, extensor carpi radialis longus; EDC, extensor digitorum communis; EDM, extensor digiti minimi; EIP, extensor indicis proprius; EPL, extensor

pollicis longus; FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis; FPL, flexor pollicis longus; IPJ, interphalangeal joint; PIPJ, proximal interphalangeal joint.

Carpal Tunnel Syndrome

- Within the carpal tunnel, synovial pannus and tenosynovitis can proliferate to the point of median nerve compression, causing carpal tunnel syndrome.
- Synovitis between the scaphoid and lunate can cause SL ligament rupture and scaphoid collapse with its distal pole protruding into the carpal tunnel.

Joints of the Hand

- In RA patients, the MCPJs and PIPJs are primarily affected, with relative sparing of the DIPJs. Radiographs reveal joint space narrowing from cartilage degradation and marginal bony erosions from pannus invasion. Joint capsules and collateral ligaments are stretched and invaded by pannus as well, leading to joint instability and deformity.
- The radial and ulnar sagittal bands stabilize the extensor tendon over the dorsal midline of the MCP joint (**FIG 5A,B**). When the radial sagittal band is attenuated, the extensor tendon subluxes ulnarly, leading to ulnar deviation of the finger (**FIG 5C**). The MCPJs in RA patients are typically characterized by volar subluxation and ulnar deviation (**FIG 5D,E**). The MCPJ is a condylar joint, allowing for flexion, extension, radial deviation, and ulnar deviation. The extensor tendon is stabilized over the dorsal midline of the MCPJ by the radial and ulnar sagittal bands. The sagittal bands are connected to the volar plate. Because the lateral bands pass volar to the MCPJ and dorsal to the PIPJ, intrinsic muscle contraction through the lateral bands results in MCPJ flexion and PIPJ extension.

FIG 5 • A,B. AP and lateral views of normal anatomy of extensor tendons of the finger. **C.** Anatomy of ulnar deviation deformity. **D,E.** MCPJ volar subluxation with ulnar deviation of the fingers.

- In RA patients, ulnar deviation at the MCPJ is due to three things:
 - Erosion of the dorsoradial aspect of the joint capsule
 - The radially deviated wrist position causing an ulnar approach of the extensor tendons
 - Attenuation of the radial sagittal bands leading to ulnar subluxation of the

extensor tendons

Swan-Neck Finger Deformity

- The swan-neck finger deformity (**FIG 6**) is characterized by PIPJ hyperextension with DIPJ flexion.
- This deformity is functionally debilitating due to loss of PIPJ flexion, which impedes pinching and grasping.
- Swan-neck deformities can result from pathology at the MCPJ, PIPJ, or DIPJ (Table 5).

FIG 6 • A,B. Swan-neck deformity.

Table 5 Three Mechanisms Resulting in the Swan-Neck Deformity	
Originating Joint	Mechanism of Swan-Neck Deformity
DIPJ	• Initially, the terminal tendon attenuates or erodes, resulting in a mallet finger. • This leads to increased extension at the PIPJ through the central slip, which is accentuated by MCP flexion. • Further attenuation of the PIP volar plate from synovitis leads to PIPJ hyperextension.
PIPJ	• Initially, the synovial pannus stretches and erodes the volar plate and capsule, allowing for PIPJ hyperextension. • The lateral bands slide dorsally, leading to extra slack in the extensor mechanism. • Slack in the extensor mechanism, combined with tightening of the flexor digitorum

	profundus (FDP) tendon, leads to DIPJ flexion.
MCPJ	• The volarly subluxed MCPJ posture leads to excessive pull through the extensor mechanism. • When the lateral bands migrate dorsally, the resulting tendon imbalance leads to PIPJ hyperextension and DIPJ flexion.

Boutonniere Finger Deformity

- Boutonniere deformities are less common than swan-neck deformities. They are also less debilitating given that PIPJ flexion, and thus, pinch and grasp are preserved.
- The pathology of boutonniere deformities always starts at the PIPJ, where disruption of the central slip at the base of the middle phalanx occurs. The dorsal capsule, transverse retinacular ligament, and triangular ligament also attenuate. As such, the lateral bands sublux to a position volar to the axis of the PIPJ, flexing the PIPJ.
- Hyperextension at the DIPJ occurs because the lateral bands continue to pull distally on the extensor mechanism at the terminal tendon (**FIG 7**).

FIG 7 • A,B. Boutonniere deformity.

Thumb Deformity (Types I to V)

- The boutonniere deformity (type I) is the most common thumb deformity in RA patients, characterized by MCPJ flexion, interphalangeal (IP) hyperextension, and radial abduction of metacarpal (**FIG 8**).

- Synovial pannus at the MCPJ erodes dorsally, causing eventual rupture of the extensor pollicis brevis (EPB) tendon insertion and displacing the EPL ulnarly and volarly. This leads to MCPJ flexion and volar subluxation. IP joint hyperextension occurs secondarily and is exacerbated in patients with FPL rupture.
- A type II thumb deformity in RA is less common, characterized by thumb MCPJ flexion and IP extension in the setting of carpometacarpal joint (CMCJ) dislocation or subluxation.
- The swan-neck deformity (type III) is the second most common deformity of the thumb, with MCPJ hyperextension, IP flexion, and a metacarpal adduction contracture (**FIG 9**).
- The volar beak ligament attenuates at the CMCJ, leading to CMCJ subluxation or dislocation and metacarpal adduction. MCPJ hyperextension occurs secondarily as the thumb compensates for the adducted metacarpal and is exacerbated by volar plate attenuation or erosion from pannus invasion.
- The type IV thumb deformity is termed the gamekeeper deformity, which develops secondary to synovial pannus destruction of the ulnar collateral ligament at the MCPJ.
- The type V thumb deformity is similar to the swan-neck deformity, with MCPJ hyperextension and IP flexion, but without the metacarpal adduction contracture.

Trigger Finger

- Trigger fingers in RA patients have a mechanism that is distinct from nonrheumatoid trigger fingers, occurring secondary to synovitis or small rheumatoid nodules in the flexor tendon.
- If the nodule is proximal to the A1 pulley, it can present similarly to a nonrheumatoid trigger digit, with locking in flexion or extension. However, a nodule just distal to the A2 pulley can result in locking in extension or triggering during flexion. Also, multiple nodules or diffuse tenosynovitis can lead to loss of flexion and extension altogether.

FIG 8 • A,B. Thumb boutonniere deformity.

- Treatment for trigger fingers in patients with RA involves flexor tendon synovectomy through windows in the flexor tendon sheath, along with excision of the rheumatoid nodule, if present.
- The A1 pulley should not be completely released, as doing so would redirect the pull of the flexor tendon and contribute to ulnar deviation.

FIG 9 • A–C. Thumb swan-neck deformity.

NONOPERATIVE MANAGEMENT

- The mainstay of RA treatment is medical, particularly with disease-modifying

antirheumatic drugs (DMARDs): glucocorticoids, methotrexate (MTX), conventional DMARDs, and biologic DMARDs.⁷ These medications prevent or reduce joint destruction, maintain or improve function, and can improve other aspects of the patient's general health. The goal of medical management in RA is not only clinical remission but also to prevent joint destruction with early medical intervention.⁶

- Oral glucocorticoids suppress inflammation and preserve joint structure. Glucocorticoids can also be injected into actively inflamed joints for pain relief.
- MTX, a folic acid antagonist, is often considered the first-line therapy for RA treatment, as it has been shown to decrease radiographic progression of the disease. MTX is potentially hepatotoxic, and the patient's liver enzymes should be checked at regular intervals. Since MTX is renally cleared, patients with chronic renal insufficiency should not be treated with MTX.
- Conventional DMARDs include hydroxychloroquine, sulfasalazine, and leflunomide, which are mild anti-inflammatory agents. These can be used single agents in mild RA or in combination with MTX or other agents.
- Biologic DMARDs include anti-TNF agents, such as etanercept, infliximab, and adalimumab. These are often used as second-line therapy for RA and can be added to MTX or other ongoing therapies. Anti-TNF agents are highly immunosuppressive and must be discontinued if an infection is encountered. Other biologic agents include abatacept and rituximab, which are safe when combined with MTX, and can be used if anti-TNF therapy has failed.
- Nonsteroidal anti-inflammatory drugs (NSAIDs) and other analgesics can be used in combination with DMARDs in the symptomatic treatment of pain in RA patients, but they do not have any significant impact on disease progression or function and should not be used as the primary or sole therapy in RA patients.
- Patients with RA should also be monitored for osteopenia and osteoporosis, which are common comorbid conditions in RA and can be accelerated with glucocorticoid therapy.
- Patients should also participate in physical and occupational therapy to maintain joint mobility and function, improve strength and endurance, and enhance cardiovascular fitness.
- Patients should be educated on the safe use of assistive devices, joint protection, and rest.

SURGICAL MANAGEMENT

- Although excellent clinical and radiographic results in patients with mild deformities or tenosynovitis have been obtained since the introduction of DMARDs, patients who develop severe joint deformities, tendon ruptures, and recalcitrant tenosynovitis will require surgical intervention.
- The management of rheumatoid hand problems requires an integrated approach involving both the rheumatologist and the hand surgeon. Once medical management is optimized, the patient can be considered for surgery in an effort to provide pain relief, improve function, prevent disease progression, and improve appearance.
- Common surgeries for the rheumatoid hand include tendon reconstruction, correction of swan-neck deformities, correction of boutonniere deformities, and silicone arthroplasty of the MCP joints.
- Tendon transfers are indicated if there is rupture of the long digital flexor or extensor tendons. A thorough tendon examination (**FIG 10**; see Table 3) is critical in determining the appropriate reconstructive options (see Table 4).
- Although the typical swan-neck deformity involves a flexion contracture of the MCPJ, hyperextension of the PIPJ, and dorsally displaced lateral bands (see **FIG 6**), treatment is based on the flexibility of the PIPJ and condition of the joint cartilage. One must test active and passive PIPJ motion with the MCPJ in extension and flexion in order to evaluate intrinsic muscle involvement.
- The Nalebuff classification⁸ is useful for surgical decision-making (Table 6).
- Flexor tendon adhesions are suspected if PIPJ active motion is not nearly equal to its passive motion. On the other hand, if the PIPJ remains flexible regardless of MCPJ position (type I), a PIPJ extension-blocking splint may be enough to correct the deformity. If PIPJ flexion is restricted with MCPJ extension and radial deviation, ulnar intrinsic muscle tightness is present.
- Reconstructive surgery can be performed for a boutonniere deformity provided that the PIPJ has full passive extension. The Nalebuff classification of boutonniere deformities (see Table 6) classifies this as stage I or II. However, if a severe fixed flexion contracture exists, or if articular destruction is present (stage III), arthrodesis or arthroplasty of the PIPJ is recommended.
- In RA patients, silicone metacarpophalangeal joint arthroplasty (SMPA) is indicated to treat MCPJ contracture, subluxation, or dislocation. However, SMPA is not indicated in patients with other rheumatic conditions such as lupus, in which soft tissue laxity is present without the underlying joint

destruction. In such patients, joint replacement would inevitably lead to joint dislocation due to the absence of healthy supporting ligaments.

- In RA patients with no evidence of MCP joint subluxation or arthritis, soft tissue reconstruction for correction of ulnar deviation finger deformities can be performed using the crossed intrinsic tendon transfer. The ulnar deviation deformity must be passively correctable. As such, this procedure is also useful in patients with lupus who do not have any underlying joint destruction.

Preoperative Planning

- Preoperative evaluation of RA patients is critical in reducing surgery-related morbidity and mortality.
- Many surgeons advocate that all RA patients should be seen in the preoperative anesthesia clinic due to a high incidence of comorbid conditions.
- A thorough evaluation with an electrocardiogram, complete blood count and differential, metabolic panel, chest radiograph, and cervical spine radiographs should be obtained.
- From a cardiac standpoint, RA can be associated with pericardial effusion, constrictive pericarditis, or conduction blocks, thereby impacting cardiac function. In addition, RA patients are at increased risk of coronary artery disease.
- Pulmonary involvement may include rheumatoid nodules, pleural effusions, or interstitial lung disease.
- Long-standing RA can be associated with Felty syndrome (splenomegaly, neutropenia, and secondary thrombocytopenia).
- Cervical spine flexion-extension radiographs are imperative as atlantoaxial instability is common in RA patients, placing patients at risk for spinal cord injury with routine procedures such as endotracheal intubation.
 - Patients with cervical instability should undergo fiberoptic intubation.
 - RA may also involve the cricoarytenoid and the temporomandibular joints, which can further complicate airway management.

FIG 10 • Tendon examination maneuvers. **A.** Check EPL by placing patient's palm down on tabletop and asking patient to lift the thumb. **B.** Check EIP and EDM by asking patient to extend the index and small fingers only. **C.** Check FDS of each digit by blocking all other digits and asking the patient to bend the digit in question. **D.** Check FDP by blocking the patient's

middle phalanx and asking patient to bend the fingertip. **E.** Check FPL by blocking the patient's thumb proximal phalanx and asking patient to bend thumb. **F.** Check the extensor tendons by flexing the patient's wrist and seeing if the fingers extend (the tenodesis effect).

Table 6 The Nalebuff classification for swan-neck deformities and surgical options

Type	Description	Surgical Goals/Options
I	PIPJ is flexible in all positions of the MCPJ	Must limit PIPJ hyperextension (splint, dermodesis, FDS tenodesis) and restore DIPJ extension (tenodermodesis, fusion)
II	PIPJ flexion is limited in certain MCPJ positions	Intrinsic release and/or MCPJ arthroplasty, in addition to procedures required for type I deformities
III	PIPJ flexion is limited irrespective of MCPJ positions	Restore PIPJ flexion by manipulation, lateral band mobilization, and lengthening of central slip
IV	PIPJ joints are stiff, with poor radiographic appearance	Arthrodesis of PIPJ is preferred, but implant arthroplasty may be considered

DIPJ, distal interphalangeal joint; FDS, flexor digitorum superficialis; PIPJ, proximal interphalangeal joint; MCPJ, metacarpophalangeal joint.

- Perioperative medication management should be discussed with the patient's rheumatologist. In general, corticosteroids can be continued, but patients may require a stress dose at the time of surgery.
- MTX and other conventional DMARDs can generally be continued.
- Biological DMARDs, on the other hand, are typically discontinued for 2 to 4 weeks before and after surgery. Again, discussion with the patient's rheumatologist is imperative.

Positioning

- Patients are positioned supine with the upper extremity abducted on a hand

table.

- Care is taken to provide the appropriate neck support.
- A tourniquet is placed on the upper arm.

TECHNIQUES

■ Tendon Transfers for Tendon Ruptures

Imaging and Planning

- Radiographs of the wrist to evaluate the DRUJ, midcarpal joint, and radiocarpal joint should be obtained.
 - Should these joints be involved, they must be addressed at the time of tendon reconstruction to prevent progressive deformity and rerupture of the reconstructed tendons.
- If tendon rupture is diagnosed, surgical reconstruction is indicated to restore function. Because the ruptured tendon ends are of poor quality, direct repair is usually not possible. Furthermore, myostatic contraction eventually leads to loss of the proximal end of the ruptured tendon, preventing the use of tendon grafts. Tendon transfer is the preferred reconstructive option.
- Depending on the number of ruptured tendons, surgery may involve a simple end-to-side repair to an intact adjacent tendon, or it may require transfer of a new motor-tendon unit (Table 5). It is also important to address the cause of tendon rupture at the time of tendon reconstruction to prevent rerupture.
 - If synovitis is the cause, a synovectomy must also be performed.
 - If joint instability or bony erosion is the cause, a procedure to address this should be performed as well.

Tendon Transfers for Extensor Tendon Ruptures

- After tourniquet inflation, a 6-cm longitudinal incision is made over the dorsal wrist in line with the long finger.
- Skin flaps are raised to expose the extensor retinaculum.
- The retinaculum is incised and elevated using a stair-step design (**TECH FIG 1A**).
 - The stair-step incision effectively lengthens the retinaculum to permit closure over the reconstructed tendons in the presence of swelling.

- Also, if there is eroded bone exposed at the radiocarpal joint, half of the retinaculum can be used as a protective layer between bone and tendon, while the other half is closed over the tendons.
- Next, the septa between the second and sixth extensor compartments are divided, bringing the tendons together, typically revealing hypertrophic synovial tissue encasing the tendons (**TECH FIG 1B**).
- Synovectomy is then sharply performed. Tendons that are invaded by synovial tissue are also completely excised (**TECH FIG 1C**).
- Tendon reconstruction then proceeds based on the tendons involved (see Table 4). All tendon junctures are secured with nonabsorbable braided suture (**TECH FIG 1D**).
- If EPL is to be addressed, a separate incision is made at the level of the thumb metacarpal, to identify the distal EPL tendon (**TECH FIG 1E**).
- The EIP tendon is often weaved into the EPL tendon (**TECH FIG 1F**), thereby restoring EPL function (thumb retropulsion).
- If three or more extensor tendons are ruptured, the FDS is used for the transfer.
 - The FDS tendon is identified through a transverse incision in the distal palm and divided. The proximal end of the tendon is retrieved via a separate longitudinal incision in the distal volar forearm and passed in a subcutaneous tunnel radially in order to reach the extensor tendons on the wrist dorsum.
 - A single FDS tendon can be transferred to up to three extensor tendons. If more than three extensor tendons are ruptured, however, transfer of both the ring and long finger FDS tendons should be considered.
- Once all tendons are addressed, the dorsal wrist capsule is closed using braided sutures. If the capsule is lax, it can be imbricated with these sutures.
- The forearm is placed in supination, and the capsule over the distal ulna is closed tightly with 3-0 braided sutures in a horizontal mattress fashion.
- Next, the extensor tendons are re-examined for laxity.
 - If lax, the extensor tendons can be tightened with horizontal mattress braided sutures.
 - Tension is set with all fingers in fully extended posture, as some postoperative stretching is anticipated.
- The extensor retinaculum is then repaired. If needed, the distal half can be used to augment the wrist capsular repair, placing it underneath the extensor

tendons, and the proximal half is sutured over the tendons, recreating the pulley (**TECH FIG 1G**).

- The tourniquet is then released, hemostasis is achieved, and the skin is closed with 4-0 nylon simple interrupted sutures.
- Fingers are immobilized in fully extended position for 4 weeks, and then active range-of-motion (ROM) exercises are initiated.

Reconstruction of Ruptured Flexor Tendons

Grafting for FPL Rupture

- For the treatment of an FPL rupture caused by attritional wear against an eroded scaphoid (Mannerfelt lesion), exposure of the tendon is performed at the palm-wrist junction, and initially, a flexor tenolysis is performed.
- The osteophyte is then removed with a rongeur, and the capsule is closed to provide a smooth gliding surface.
- If the proximal and distal ends of the ruptured FPL tendon can be found within the palm-wrist incision, a small bridge graft from the palmaris longus (PL) is used in a Pulvertaft weave with 3-0 nonabsorbable braided horizontal mattress sutures (**TECH FIG 2**).
 - As an alternative, a strip of the FCR can be used instead of the PL.

Tendon Transfer for FPL Rupture

- If grafting within the palm or wrist is not possible, a tendon transfer is required. Here, the long finger FDS tendon transfer for FPL reconstruction is described.
 - A zigzag incision is made in the palm and the long finger FDS tendon is identified (**TECH FIG 3A**).
 - The long finger FDS is divided and brought into the palmar wound (**TECH FIG 3B,C**).
 - Through a Bruner incision on the thumb, the flexor tendon sheath is sharply opened and divided transversely, leaving enough tendon distally for suturing.

TECH FIG 1 • Tendon transfer for extensor tendon reconstruction. **A.** Extensor retinaculum with stair-step design. **B.** Hypertrophic synovial tissue encasing extensor tendons. **C.** Extensor tendon ends after debridement (prior to reconstruction). **D.** Extensor tendon reconstruction with sutures in place. **E.** Exposure of EPL through separate thumb incision. **F.** EIP woven into EPL tendon. **G.** Reconstruction of extensor retinaculum (half under and half over the extensor tendons).

TECH FIG 2 • Ruptured flexor pollicis longus tendon reconstruction with PL. **A.** Planned skin incisions. **B.**

Ruptured FPL tendon is identified at the wrist. **C.** FPL with excellent excursion. **D.** FPL is attached to PL. **E.** PL to FPL tendon reconstruction. **F.** Pulvertaft weave.

- The FDS is then delivered into the flexor tendon sheath of the thumb using a pediatric feeding tube.
- Nonabsorbable braided suture is then used to sew the FDS tendon to the distal FPL tendon (**TECH FIG 3D**). Tension should be set so that IP extension occurs with wrist flexion, and full flexion into the palm occurs with wrist extension.

Isolated FDS or FDP Ruptures

- If an isolated FDS rupture occurs within the palm or carpal tunnel, an end-to-side suture using a Pulvertaft weave to an adjacent FDS is performed, along with flexor tenosynovectomy and the smoothing of any sharp bony edges.
 - However, if the FDS rupture occurs within the finger, a tenosynovectomy with resection of the FDS should be performed.
- Similarly, if an isolated FDP rupture occurs within the palm or wrist, an end-to-side suture to an adjacent FDP is performed.
- If FDP rupture occurs within the finger, as long as FDS is still functional, the FDP is resected.
- If the DIPJ hyperextends during pinch or grip, DIP arthrodesis is performed as well.

Combined FDS and FDP Ruptures

- If occurring within the palm or wrist, the combination rupture of both FDS and FDP is treated with end-to-side suturing of the FDP to an adjacent tendon.
 - Alternatively, a bridge graft from the ruptured FDS can be used to repair the FDP tendon.
- If both FDS and FDP have ruptured within the flexor tendon sheath, a staged reconstruction should be considered, though outcomes in patients with RA are often disappointing due to limited recovery of motion.
- In patients with IPJ arthritis, the best option is arthrodesis of the PIP and DIP joints in a functional position, with preservation of some finger motion at the MCPJ via the intrinsic system.

TECH FIG 3 • Long finger FDS tendon transfer for ruptured flexor pollicis longus tendon reconstruction. **A.** Long finger FDS is identified through a palmar incision. **B.** The FDS is divided and retracted into palmar wound. **C.** The FDS is transferred from the long finger to the FPL tendon through a Bruner incision on the thumb. **D.** The reconstructed FPL tendon is shown.

■ Postoperative Care

- If tendon transfers are performed for flexor reconstruction, the hand and fingers are immobilized in a dorsal blocking splint to take tension off the transfers for 3 to 4 weeks.
- After this period, ROM exercises are gradually initiated, as guided by the hand therapist.

■ Correction of Swan-Neck Deformity

- It is imperative to understand the anatomy of the extensor apparatus of the finger (see **FIG 5**).

Correction of PIPJ Hyperextension (Type I to III Deformities)

FDS Tenodesis (“Lasso”)

- This is the authors’ preferred technique.
- A slip of FDS is divided proximal to the A2 pulley (**TECH FIG 4A**).
- A hole is made in the distal third of the proximal phalanx, from the volar to lateral surface (**TECH FIG 4B**).
- The FDS slip is passed through the hole, from volar to lateral (**TECH FIG 4C**), and is sutured with the PIPJ at 20 to 30 degrees of flexion (**TECH FIG 4D**).
- This procedure can be combined with removal of a small ellipse of skin at the PIPJ to reinforce the tenodesis, particularly in lupus patients.

Retinacular Ligament Reconstruction

- The ulnar lateral band at the midproximal phalanx is divided and dissected distally (**TECH FIG 5A**).
- It is passed volar to the Cleland ligament, such that the ulnar lateral band can maintain the PIPJ in flexion (**TECH FIG 5B**).
- The lateral band is sutured to the A2 pulley or into the bone of the proximal phalanx to maintain PIPJ flexion at 20 to 30 degrees (**TECH FIG 5C**).
- An extension block pin is placed to protect the reconstruction.

Bone Anchor Repair of Volar Plate

- A Bruner (zigzag) incision is made on the volar finger surface.
- The accessory collateral ligament is identified and incised in order to retract the volar plate and flexor sheath laterally, exposing the head of the proximal phalanx.

TECH FIG 4 • FDS tenodesis for correction of swan-neck deformity. **A.** An FDS slip is divided proximal to A2 pulley. **B.** A hole is drilled in the proximal phalanx (distal third), from volar to lateral surface. **C.** FDS slip is passed through the hold from volar to lateral. **D.** FDS slip is sutured with PIPJ at 15 to 20 degrees of flexion.

- A drill hole is made in the center of the volar surface of the proximal phalanx, approximately 5 to 7 mm proximal to the joint line.
- A bone anchor, which is connected to two needled sutures, such as the Mitek Mini (Mitek Surgical Products Inc., Norwood), is placed into the hole.
- One needled suture is passed from the dorsolateral volar plate, emerging at the central volar plate, and then passed through the edge of the previously divided accessory collateral ligament. The suture is tied with the goal of maintaining 10 degrees of PIPJ flexion.
- The other needled suture is then passed in a similar fashion on the other side and then tied with the PIPJ at about 20 to 30 degrees of flexion.
- Note that this procedure is technically difficult to perform and is not the

authors' preferred technique.

TECH FIG 5 • Retinacular ligament reconstruction for correction of swan-neck deformity. **A.** The ulnar lateral band is exposed at midproximal phalanx. **B.** The ulnar lateral band is passed volar to the Cleland ligament. **C.** The ulnar lateral band is sutured to the A2 pulley.

Correction of DIPJ Flexion Deformity (Type I to IV Deformities)

Dorsal Tenodermodesis of the DIPJ

- A transverse ellipse of skin is excised at the dorsal DIPJ.
- A 3-0 nylon horizontal mattress suture is placed through the skin and underlying extensor tendon in order to close the skin gap. With the DIPJ held in extension, the suture is tied.
- A K-wire is inserted obliquely through the extended DIPJ and is cut off beneath the skin.
- In general, this technique is not preferred because patients have thin skin and tend to experience complications.

DIPJ Arthrodesis

- An H- or Y-incision over the dorsal DIPJ is made to expose the extensor tendon.
- The extensor tendon and collateral ligaments are divided, allowing the joint to be hinged open.
- The joint surfaces are sculpted with a small bur, creating a “trough” distally and a “crest” proximally.
- The bone is fit together, and a compression screw is placed across the joint to support bony fusion. (See chapter on Degenerative Disease of the Hand and Wrist for details).

Correction of a Stiff Swan-Neck Deformity (Type III Deformity)

Lateral Band Mobilization

- A curved incision is made over the extensor apparatus overlying the proximal phalanx to the mid middle phalanx (**TECH FIG 6A**).
- The lateral bands are typically found to be dorsally displaced and adherent to the central slip, causing the extension contracture. The lateral bands are sharply dissected from the central slip (**TECH FIG 6B**), distal to proximal, preserving a wide central slip, particularly when the demarcation between the central slip and lateral bands is unclear.
 - A wider central slip can better resist accidental rupture during joint manipulation and is easier to lengthen.
- Next, the PIPJ is flexed to enable the lateral bands to move laterally and volarly (**TECH FIG 6C**).
 - If it is difficult to flex the PIPJ, the dorsal capsule and dorsal aspects of the collateral ligaments may need to be release.
 - Care must be taken to monitor the tension of the central slip during PIPJ manipulation to avoid rupture.

Step-Cut (Z) Central Slip Lengthening

- This procedure can be considered if the central slip continues to restrict PIPJ flexion after release of the lateral bands and attempted PIPJ manipulation. It is generally not necessary, however, because the central slip tends to stretch over time with therapy.
- A Z-incision of the central slip is made, starting 3 to 4 mm proximal to its insertion at the middle phalanx. It is extended 1 to 1.5 cm proximally.
- If not yet performed, the dorsal capsule and dorsal portions of the collateral ligaments are sharply released.

- With the PIPJ in slight flexion, the central slip is then repaired with at least three or four horizontal mattress sutures to prevent rupture during early mobilization.

TECH FIG 6 • Lateral band mobilization for correction of stiff swan-neck deformity. **A.** Exposure of extensor apparatus from proximal to mid middle phalanx. **B.** The lateral bands are identified and separated from the central slip. **C.** The PIPJ is flexed, allowing the lateral bands to fall volarly

■ Postoperative Care

- Active motion is initiated on the 2nd postoperative day.
- A dorsal extension block splint is applied for 2 weeks until the skin has healed. Then, a thermoplastic figure-eight splint is applied for an additional 8 weeks.
- After lateral band mobilization and manipulation of the PIPJ for a type III deformity, the PIPJ should be splinted in flexion in order to stretch the dorsal

soft tissue.

- Patients should continue active flexion exercises, except in cases in which central slip lengthening was also performed.

■ Ligament Reconstruction to Correct Boutonniere Deformity

- Once the patient is made comfortable with a wrist or digital block, a dorsally placed curved incision over the PIPJ is made to expose the extensor apparatus.
- The lateral bands and transverse retinacular ligaments are identified.
- The radial and ulnar transverse retinacular ligaments are sharply divided from their insertions on the volar plate of the PIPJ.
- The transverse retinacular ligaments are then turned over dorsally on either side of the PIPJ and sutured together.
 - Tension of the suture is determined by asking the patient to actively extend the PIPJ.
 - Tension should be set at the near-full extended position.
- Next, active flexion of the DIPJ must be checked. If DIPJ flexion is limited, small transverse cuts into the lateral bands to lengthen them between the PIPJ and DIPJ (overlying the distal half of the middle phalanx) should be made, until the DIPJ can be actively flexed to 30 degrees.
- The PIPJ is then immobilized in full extension with a K-wire for 2 weeks.

■ Postoperative Care

- Within 3 days of surgery, active DIPJ flexion exercises are initiated, while the PIPJ remains immobilized.
- At about 2 weeks, active PIPJ flexion exercises are begun, while active extension exercises should be avoided.
- To keep the PIPJ in full extension, a daytime dynamic splint and nighttime static splint should be provided.
- The splint is gradually weaned, and active finger exercises are slowly advanced under the guidance of a hand therapist.

■ Silicone Metacarpophalangeal Joint Arthroplasty

- The patient is positioned supine with the extremity abducted on a hand table.
- Under tourniquet control, a transverse incision is made over the heads of the second through fifth metacarpals, taking care to preserve the dorsal veins and sensory nerves (**TECH FIG 7A**).
- The radial sagittal bands are divided to expose the MCPJs. Synovectomy is performed sharply.
- The collateral ligaments are divided at the metacarpal neck, taking care to preserve the radial collateral ligament insertion on the proximal phalanges for later reconstruction.
- With an oscillating saw, the metacarpal heads are resected at the proximal origin of the collateral ligaments (**TECH FIG 7B**).
 - After metacarpal head resection, the fingers are brought into alignment.
 - Using a twisting motion, an awl is used to perforate the medullary cavities of the metacarpals and proximal phalanges (**TECH FIG 7C**).
- Next, sequentially sized broaches are used to enlarge the medullary cavities of the proximal phalanges first, then the metacarpals, since the size of the phalangeal cavity usually determines the implant size to be used.
 - The exception is the ring metacarpal, which is typically narrower than the ring finger proximal phalanx and should thus be prepared first to avoid over-reaming the proximal phalanx.
 - It is important that the broach is inserted straight without twisting, making a rectangular trough to accommodate the shape of the silicone implants.
- The largest implants that will fit into the medullary cavity are then selected.
- Prior to implant insertion, two drill holes are made with a 0.035-in. K-wire on the radial edge of the metacarpal (**TECH FIG 7D**)
 - 3-0 braided permanent sutures are placed through these drill holes to reconstruct the radial collateral ligaments (**TECH FIG 7E**).
- Next, the implants are inserted (**TECH FIG 7F**).
- The radially placed sutures are used to reattach the radial collateral ligament, bringing the fingers into slight radial deviation (**TECH FIG 7G**).
- If still tight, the ulnar lateral bands can be released, though this is usually not necessary.
- The position of the extensor tendons should be re-evaluated. If they cannot be centralized easily, the ulnar sagittal bands may also need to be released.

- Next, the extensor tendons are centralized by imbricating the radial sagittal bands with 3-0 braided horizontal mattress sutures.
- The tourniquet is released, and hemostasis is achieved.
- The skin is closed with absorbable dermal sutures followed by 4-0 horizontal mattress nylon sutures (**TECH FIG 7H**).
- A volar resting short-arm splint is applied.

TECH FIG 7 • Silicone metacarpophalangeal joint arthroplasty. **A.** A transverse incision is made over the metacarpal heads. **B.** The metacarpal heads are resected with an oscillating saw. **C.** An awl is used to perforate the medullary cavities of the metacarpals and proximal phalanges. **D.** Two drill holes are made on the radial edge of the metacarpal. **E.** Sutures are placed through the drill holes. **F.** The silicone implants are inserted. **G.** The sutures are tied down, thereby reconstructing the radial collateral ligament. **H.** Skin closure, improved alignment of fingers

■ Postoperative Care

- The patient is placed in a dynamic extension splint 1 week postoperatively.
 - While in the splint, the patient is to begin active flexion exercises for 6 weeks under the guidance of a hand therapist. The splint is adjusted as necessary to align the fingers.
-

■ Crossed Intrinsic Transfer for Correction of Ulnar Deviation Deformity

Pertinent Anatomy

- The radial and ulnar sagittal bands stabilize the extensor tendon over the dorsal midline of the MCP joint (see **FIG 5A**). When the radial sagittal band is attenuated, the extensor tendon subluxes ulnarly, leading to ulnar deviation of the finger (see **FIG 5C**).
- On the ulnar side of the digit, the common intrinsic tendon is formed by the tendons of the palmar and dorsal interosseous muscles. On the radial side, the common intrinsic tendon is formed by the tendons of the interosseous muscles as well as the lumbrical.
- The common intrinsic tendon then passes volar to the MCP joint and divides into a medial band (which inserts into the central slip at the dorsal base of the middle phalanx) and a lateral band (which inserts at the dorsal base of the

distal phalanx).

- Thus, intrinsic muscle contraction results in MCP joint flexion and IP joint extension.
- In a cross intrinsic transfer, the common intrinsic tendon is divided distally (slanted lines) and sutured to the extensor tendon of the adjacent finger (**TECH FIG 8**).

TECH FIG 8 • Cross intrinsic transfer for repair of the index finger radial sagittal band. The common intrinsic tendon is divided distally (*slanted lines*) and sutured to the extensor tendon of the adjacent finger (*arrows*).

■ Transfer Procedure

- Under tourniquet control, the extensor apparatus over the MCP joint is exposed through a lazy-S incision if only one finger is involved or through a dorsal transverse incision over the MCP joints if multiple fingers require correction (**TECH FIG 9A**).

- A longitudinal incision paralleling the extensor tendon is made through the attenuated radial sagittal band (**TECH FIG 9B**).
- The MCP joint is opened. A synovectomy is performed.
- On the ulnar side, the common intrinsic tendon is identified (**TECH FIG 9C**) and divided from its attachment to the extensor mechanism at the midproximal phalanx.
- The tendon is rerouted across the adjacent web space to reach the extensor tendon of the digit ulnar to it (**TECH FIG 9D**). It is then passed through a slit made at the midportion of the extensor tendon overlying the MCP joint and sutured to itself using 3-0 braided nonabsorbable suture.
 - Note that the ulnar common intrinsic tendon of the index finger is used to correct the long finger; the tendon of the long finger is used to correct the ring finger; and the tendon of the ring finger is used to correct the small finger.
- The index finger is then corrected by a double-breasted repair of the radial sagittal band (**TECH FIG 9E**).
- The skin is closed with simple interrupted horizontal mattress sutures (**TECH FIG 9F**).

TECH FIG 9 • **A.** Planned skin incision over the MCP joints. **B.** The attenuated radial sagittal band of the long finger is incised to access the MCP joint to facilitate synovectomy. **C.** The ulnar common intrinsic tendon of the long finger is identified. **D.** The ulnar common intrinsic tendon of the ring finger has been rerouted to the small finger to be sutured to the

extensor tendon. The intrinsic tendon is being held by the clamp in this photo. **E.** Final appearance of multiple cross intrinsic tendon transfers to the long, ring, and small fingers. A double-breasted repair of the radial sagittal band of the index finger is also shown. **F.** Skin closure.

■ Postoperative Care

- A volar hand splint is placed to support the reconstruction with the MCP joint in extension.
- At 10 days, a removable splint is placed.
- At 4 weeks, a gradual mobilization protocol is initiated with protective splinting for another 4 weeks.

PEARLS AND PITFALLS

TENDON TRANSFERS FOR TENDON RUPTURES

Extensor tendon exposure	■ Skin flaps are raised superficial to the extensor retinaculum, taking care to preserve the longitudinal dorsal veins (improves postoperative swelling) and superficial sensory nerve branches. ■ Skin must be handled as gently as possible, as skin quality and vascularity are already impaired by rheumatoid disease and/or medications.
Stair-step incision of extensor retinaculum	■ Facilitates closure of the extensor retinaculum at the end of the case, as swelling under retinaculum is common. ■ Can be useful to shield the extensor tendons from the radiocarpal joint in cases of bony erosion (half the retinaculum is placed under the extensor tendons, and the other half is used to close over them).
Treatment of combined ring and small finger extensor tendon ruptures	■ Treatment options include EIP transfer or end-to-side repair of the ring and small finger extensor tendons to the long finger extensor tendon. ■ EIP transfer is preferred due to the line of pull. ■ End-to-side repair to the long finger extensor tendon results in

	an oblique pull that can cause unwanted abduction of the small finger.
Transferring FDS tendons	■ For extensor tendon reconstruction, a subcutaneous transfer is preferred over a transfer through the interosseous membrane (high risk of adhesions). ■ A subcutaneous transfer on the radial side is preferred over the ulnar side, because the direction of pull helps to correct the ulnar deviation deformity.
Thumb interphalangeal joint (IPJ) fusion	■ Can be considered as long as the MCPJ is stable and functional and the strength of intrinsic muscles is adequate. If not, the patient will not achieve satisfactory pinch strength.
Darrach procedure	■ Defined as the resection of the head of the ulna. ■ May be required if the distal ulna is the source of tendon attrition and rupture. ■ If performed concomitantly with tendon reconstruction, a supination splint should be placed for 4 weeks postoperatively.
CORRECTION OF SWAN-NECK DEFORMITY	
Exposure	■ Avoid injury to the digital nerve at the tip of the flap where it is just beneath the skin by identifying the nerve at the base of the flap.
Dorsal DIPJ tenodesis	■ Generally, soft tissue reconstruction for DIPJ extension is discouraged, and arthrodesis is preferable. ■ However, tenodesis combined with DIPJ pinning for greater than 2 months can create a generally stiff DIPJ allowing for slight motion.
LIGAMENT RECONSTRUCTION TO CORRECT BOUTONNIERE DEFORMITY	
Preoperative management	■ Passive PIPJ mobility is critical to optimize surgical outcomes after correcting a boutonniere deformity. ■ If a severe PIPJ flexion contracture is present, rehabilitation and extension splinting should be performed prior to surgery.
Imaging	■ Radiographs are required to evaluate MCJP, PIPJ, and DIPJ status prior to surgery. PIPJ destruction indicates the need for arthrodesis or arthroplasty, as opposed to ligament reconstruction. ■ MRI may be helpful in identifying synovitis of the PIPJ but is expensive and not usually necessary to make the diagnosis.

Anesthesia: wrist or digital block	■ The surgery is done under a wrist or digital block such that the patient can perform active finger motion during the operation to allow for proper tension setting.
Tension setting	■ The transverse retinacular ligaments are sutured together at the dorsal aspect of the PIPJ when it is in near-full extension. ■ If set too tight, the tension may lead to extension contracture of the PIPJ and DIPJ.
PIPJ contracture	■ If a contracture exists at the PIPJ, the accessory collateral ligament and proximal volar plate should be released to obtain full passive PIPJ extension. ■ Care must be taken to preserve the true collateral ligaments to prevent PIPJ instability.
Achieving DIPJ flexion	■ In some cases, dividing the oblique retinacular ligament is necessary to obtain DIPJ flexion. ■ Avoid releasing the lateral bands too far, as this can result in DIPJ extension lag.
PIPJ synovectomy	■ For patients with active RA, PIPJ synovectomy is required.

SILICONE METACARPOPHALANGEAL JOINT ARTHROPLASTY

Surgical considerations	■ If the patient's fingers are ulnarly drifted without evidence of MCPJ dislocation, soft tissue reconstruction can be performed instead of SMPA. ■ A crossed intrinsic transfer may be performed to correct finger misalignment of the small, ring, and long fingers (see crossed intrinsic transfer for ulnar deviation technique below). ■ For the index finger, the radial sagittal band must be tightened to centralize the extensor tendon, given that there is no ulnar intrinsic tendon available for transfer. ■ Thumb MCPJ laxity is best treated with MCPJ fusion. ■ Patients with wrist collapse and radial deviation of the metacarpals should first have their wrists addressed by fusion or arthroplasty. Not only will this enhance the outcome of SMPA, but also it will prevent early postoperative ulnar subluxation of the fingers after SMPA.
Imaging	■ PA, lateral, and oblique radiographs of the hand and wrist are important in order to evaluate joint alignment, joint congruity, and bony erosions.

Metacarpal head resection

- Resection of the metacarpal heads decreases the tightness of the ulnar intrinsic tendons that contribute to ulnar deviation of the fingers. As such, ulnar lateral band release is usually not necessary.

Preparing the medullary canals for implant insertion

- The medullary canals of the proximal phalanges, which are typically narrower than those of the metacarpals, should be prepared first since they usually determine the implant size to be used.
- The exception to this rule is the ring finger. The ring metacarpal typically has a narrower canal than does the proximal phalanx and should therefore be prepared first to avoid over-reaming the proximal phalanx.

CROSSED INTRINSIC TRANSFER FOR CORRECTION OF ULNAR DEVIATION DEFORMITY

Indications

- The crossed intrinsic transfer may also be considered for lupus patients with ulnar deviation deformities, as they do not have underlying joint destruction.

Surgical tips

- Try to preserve longitudinal dorsal veins during surgical exposure to minimize postoperative swelling.
- Avoid dividing the common intrinsic tendon too proximally, as it may not reach the extensor tendon of the adjacent finger if too short.
- Take care to preserve the neurovascular bundle volar to the common intrinsic tendon.
- Division of the abductor digiti minimi for correction of a small finger ulnar deviation deformity may be necessary.
- A double-breasted repair of the radial sagittal band is facilitated by leaving a 2- to 3-mm cuff of the sagittal band when longitudinally incising it at the beginning of the case.

OUTCOMES

- Tendon transfers in patients with preserved MCPJs reliably achieve restoration of MCPJ extension. However, in patients with volarly subluxed and arthritic MCPJs, arthroplasty and soft tissue reconstruction to restore joint alignment prior to performing tendon transfers are critical for optimizing outcomes.
- In general, tendon transfers for extensor tendon reconstruction achieve good results, though more extension lag is observed when more tendons are involved. For flexor tendons, patients with isolated ruptures in the palm or

wrist have the potential to maintain good finger function, provided that their prerupture finger function was good. However, if preruptured function was limited, outcomes will be poor regardless of the treatment provided.

- Outcomes after the combined rupture of FDS and FDP are also poor, regardless of prerupture finger function or method of treatment.
- To optimize outcomes, correcting the underlying causes of tendon rupture, such as extensor tenosynovitis, rough bony surfaces, and the caput ulna deformity, is critical in preventing the rerupture of reconstructed tendons.
- For advanced swan-neck deformities, the results of surgery can be unpredictable. Still, even if motion is lost, the flexed PIPJ position is functionally preferable to the hyperextended position. As such, as long as PIPJ hyperextension is prevented, there should be no hesitation in performing surgery for advanced swan-neck deformities.
- Patients who undergo SMPA typically gain 30 to 40 degrees of active motion at the MCPJ. Grip strength and pinch strength are unaffected by surgery, while ulnar drift, extension lag, and arc of motion significantly improve (**FIG 11**).
- The crossed intrinsic transfer can provide long-term correction of ulnar deviation deformities but may be associated with decreased active ROM at the MCP joint.

FIG 11 • Results 2 months (**A–F**) and 5 months (**G–L**) after silicone metacarpophalangeal joint arthroplasty.

Section VII: Degenerative Disease

25 Degenerative Disease of the Hand and Wrist

CHAPTER

Shoshana W. Ambani and Kevin C. Chung

DEFINITION

- Osteoarthritis (OA) is a noninflammatory degenerative joint condition of the hand and wrist that clinically affects 3% to 7% of adults.¹
- The hallmark of OA is the loss of articular cartilage, leading to joint destruction and osteophyte formation (**FIG 1**).

PATIENT HISTORY AND GENERAL FINDINGS

- OA is more common in women and usually presents in patients over 40 years of age.
- Patients generally complain of pain, swelling, and stiffness of the affected joint. Pain is usually activity related.
- Examination confirms swelling, tenderness, limited range of motion (ROM), and decreased function. Crepitus with passive ROM may also be noted.
- Thumb carpometacarpal joint (CMCJ) arthritis often leads to thumb weakness due to pain.
- Examination may reveal a positive grind test, in which pain is produced upon axial compression of the joint.
- Regarding the fingers, patients may display classic Heberden nodes on the dorsal distal interphalangeal joints (DIPJs) or Bouchard nodes on the dorsal proximal interphalangeal joints (PIPJs) (**FIG 2A**).
- Mucous cysts can also present at the DIPJ and cause nail deformities (**FIG**

2B,C).

- Pain with loss of wrist ROM compared to the contralateral side is indicative of wrist arthritis.
- Provocative testing of the distal radioulnar joint (DRUJ) with dorsal and palmar stress (a shuck test) may indicate DRUJ involvement.

IMAGING

- Standard three-view radiographs of the hand and wrist are typically sufficient for evaluation of OA.
 - Further imaging such as CT scan or MRI is usually not routine but may be useful in select situations, such as evaluating the wrist for midcarpal arthritis.
- OA is characterized by narrowed joint spaces due to loss of radiolucent articular cartilage.
 - In addition, osteophytes and loose bodies may be present.
 - Subchondral cysts and sclerosis are signs of more advanced disease (see **FIG 1**).
- Patient symptoms do not always correlate with the radiographic severity of disease. As such, interventions should be based on patient complaints and general goals.

PATHOGENESIS AND ETIOLOGY

- In *primary*, or *idiopathic*, OA, there is no identifiable cause.
 - In *secondary* OA, articular loss is a result of traumatic injury, such as intra-articular fractures, ligamentous injuries that lead to unfavorable articular load-bearing characteristics, or joint infections.
- Generally, OA develops as a result of an imbalance between the destruction and repair of articular cartilage.

FIG 1 • Radiograph of bilateral hands displays typical characteristics of osteoarthritis, including joint space narrowing (*yellow arrowheads*), osteophyte formation (*blue arrowhead*), and subchondral cyst and associated sclerosis (*red arrowhead*).

FIG 2 • A. Example of Heberden nodes (*red arrowheads*) and Bouchard nodes (*yellow arrowheads*). **B.** Mucous cyst on dorsal DIPJ of ring finger (*arrowhead*). **C.** A circular incision was used to excise the cyst down to the joint. An osteophyte was removed at the base of the cyst. A skin flap (*marked*) was advanced to close the remaining defect.

- Clefts in the articular surface and a decrease in cartilage thickness eventually progress to exposure of the subchondral bone.
- Bone density increases, as demonstrated by sclerotic changes seen on radiographs, and overly exuberant bone formation may produce osteophytes at the joint periphery. In addition, the synovial membranes become inflamed as cartilage fragments are embedded within them.
- Because of these mechanical factors and pain, joint motion is progressively lost, leading to joint stiffness as the capsule and associated ligaments contract.
- Hand
 - In the hand, OA most commonly affects the DIPJs of the fingers and the CMCJ of the thumb.

- OA then affects the PIPJs and metacarpophalangeal joints (MCPJs), respectively.
- Wrist
 - Scaphotrapezotrapezoid (STT) joint arthritis is one of the most common presentations of idiopathic OA of the wrist.
 - Other causes of primary wrist OA include avascular necrosis of the lunate (Kienbock disease) or the scaphoid (Preiser disease), which can lead to degenerative changes later on.
 - Congenital conditions, including Madelung deformity, can also alter the articular load, leading to wrist OA.
 - Secondary OA is usually trauma related and most frequently develops after distal radius fractures (DRFs), scaphoid fractures, and scapholunate ligamentous injuries.
 - Intra-articular DRFs can lead to a 91% incidence of arthritis if any degree of articular step-off remains after fracture reduction, but only an 11% incidence if a congruent articular reduction is achieved.
 - Extra-articular DRFs can also lead to wrist OA due to the development of abnormal load-bearing patterns across the wrist.
 - Up to 11% of DRFs are associated with instability of the DRUJ, leading to DRUJ arthritis.²
 - Of note, rheumatoid arthritis is the most common inflammatory arthritis to involve the DRUJ.
 - Scaphoid fractures may fail to heal in 5% to 10% of cases, leading to a pattern of carpal instability termed *scaphoid nonunion advanced collapse* (SNAC) arthritis.
 - SNAC wrist typically starts with arthritis at the radial styloid-scaphoid articulation (stage 1) and progresses to the radioscaphoid and scaphocapitate articulations (stage 2) and finally the lunocapitate articulation (stage 3).
 - Similarly, a scapholunate ligament injury can initiate progressive carpal instability and arthritis starting at the radial styloid (stage 1) and progressing to the proximal scaphoid and scaphoid fossa of the radius (stage 2) and finally the midcarpal joint at the lunocapitate articulation (stage 3).
 - This is cumulatively known as *scapholunate advanced collapse* (SLAC) arthritis.
 - The radiolunate joint is typically spared in the SLAC wrist because of the unique congruency of this joint.

NONOPERATIVE MANAGEMENT

- Because there is no cure for OA and no effective method to alter disease progression, the mainstay of treatment is nonoperative and focuses on symptom management.
- Patients may engage in lifestyle modifications, hot and cold therapy, splinting, oral or topical anti-inflammatory medications such as nonsteroidal anti-inflammatory drugs (NSAIDs), or alternative methods such as acupuncture or electrostimulation.
- Steroid injections into the affected joints may provide short-term relief.

SURGICAL MANAGEMENT

Preoperative Planning

- As OA patients are typically older with multiple comorbid conditions, a full medical workup is recommended prior to surgery.

Positioning

- The patient is positioned supine on the operative table and padded comfortably.
- The upper extremity is abducted onto the attached hand table.
- A tourniquet is placed on the upper arm.

Approach

- The indications for surgery in OA patients include refractory pain, loss of motion, and/or joint instability leading to decreased function.
- Surgical methods for the treatment of OA generally involve joint debridement, arthrodesis, arthroplasty, and load-altering procedures.

Fingers

- Because the DIPJs are the most commonly affected joints in OA, surgery typically involves the removal of an enlarged osteophyte and/or excision of a mucous cyst.
 - If the joint is destroyed, arthrodesis at about 5 to 10 degrees of flexion is preferred.
- The PIPJs are treated with arthrodesis or arthroplasty.
- For the radial digits, arthrodesis of the PIPJs with K-wires, screws, or tension banding is preferred in order to provide a strong post for pinch.

- The PIPJ of the index finger should be fused at 25 degrees of flexion, advancing by 5 degrees with each finger ulnarly, if required, for the most functional posture.
- The PIPJs of the ulnar digits require more motion for grip, however, and should be considered for arthroplasty.
 - Silicone arthroplasty provides limited motion to the PIPJs (30–60 degrees) and has a high fracture rate but can easily be revised.
 - Pyrocarbon implants provide greater motion, but implant dislocation may occur, and high complication rates have led to this approach falling out of favor for PIPJs.
 - We have abandoned the pyrocarbon implant in favor of the silicone implant using the volar approach for the PIPJ.

Thumb

- As the second most commonly affected joint in OA, the thumb CMCJ (ie, the trapeziometacarpal [TM] joint) is surgically treated with volar ligament reconstruction, arthroplasty, or arthrodesis.
 - Although the initial treatment may consist of splinting or steroid injections, most patients presenting to surgeons already have sufficient joint destruction to warrant surgery.
- The Eaton classification^{3,4} (Table 1) of TM osteoarthritis describes and categorizes the radiographic progression of the disease. However, surgical planning is based on patient symptoms and complaints, not Eaton classification.
- For early OA (Eaton stage I), which may be characterized symptomatic instability or laxity of the thumb TM joint, volar ligament reconstruction is indicated (Eaton-Littler procedure).
- For Eaton stage II to IV disease, loss of articular cartilage precludes the possibility of joint salvage. Surgical options fall into four major categories:

Table 1 Eaton Classification of Trapeziometacarpal (TM) Osteoarthritis^{3,4}

Stage	Radiographic Characteristics
I	• Normal or slightly widened TM joint • TM subluxation up to 1/3 of articular surface • Normal articular contours
II	

	• Decreased TM joint space • TM subluxation up to 1/3 of articular surface • Osteophytes or loose bodies less than 2 mm
III	• Decreased TM joint space • TM subluxation greater than 1/3 of articular surface • Osteophytes or loose bodies greater than or equal to 2 mm • Subchondral cysts or sclerosis
IV	• Pantrapezial arthritis with stage III features • Involvement of the scaphotrapezial, trapeziotrapezoid, and/or the trapezio-index metacarpal joints

- Trapeziectomy alone
- Trapeziectomy with soft tissue arthroplasty via ligament reconstruction and tendon interposition (LRTI) or an abductor pollicis longus (APL) suspensionplasty
- Arthrodesis
- Prosthetic arthroplasty
- Because of high complication rates with prostheses and lack of outcomes data to show their effectiveness over autologous options, we do not advocate the use of a prosthesis for the thumb TM joint.
- For heavy laborers, thumb TM arthrodesis is preferred for joint stability and strength.⁵ In these cases, the thumb TM joint should be fused at 30 to 40 degrees of abduction, 15 to 20 degrees of extension, and 15 degrees of pronation to allow tip-to-tip pinch.
- In any case, the presence of thumb MCPJ instability or hyperextension greater than 30 to 45 degrees may also warrant concomitant volar plate advancement or MCPJ fusion to avoid failure of the reconstructed TM joint.

Wrist

- Surgical treatment of wrist OA is focused on pain reduction. The specific treatment is formulated based on the patient's symptoms, arthritic pattern, and functional demands.
- The selected approach should always account for future additional procedures should the most current option fail.
- In general, surgical options include joint debridement, denervation, arthroplasty, partial vs total wrist arthrodesis, or a combination thereof.

- A radial styloidectomy can be performed for arthritis at the radial styloid.
- Wrist denervation is an option that has been shown to provide partial pain relief in patients and can be considered if selective blocks of the anterior interosseous nerve (AIN) and posterior interosseous nerve (PIN) prove favorable.
- A proximal row carpectomy (PRC), in which the scaphoid, lunate, and triquetrum are removed, is an option when there is no arthritis at the midcarpal joint or radiolunate joint.
- Midcarpal and radiocarpal arthritis can be treated with a scaphoidectomy and four-corner fusion, in which the scaphoid is removed and fusion of the lunate, capitate, triquetrum, and hamate is performed.
- For the arthritic DRUJ, surgical options include resection arthroplasties, including the Darrach procedure, hemiresection ulnar arthroplasty, the Sauve-Kapandji procedure, and prosthetic replacement of the ulnar head or DRUJ.²
 - The Darrach procedure involves resection of the entire distal ulna and has been advocated for low-demand elderly patients.
 - The Sauve-Kapandji procedure preserves the head of the ulna while fusing the DRUJ to prevent ulnar translocation of the carpus.
 - Hemiresection ulnar arthroplasty, in which the radiocarpal joint surface of the ulna is resected while maintaining the triangular fibrocartilage complex (TFCC), is often preferred over the Darrach procedure because of improved postoperative wrist stability. Prosthetic replacement of the ulnar head or DRUJ is a less common option for the arthritic DRUJ.
- In cases of significantly advanced arthritis, wrist arthroplasty or fusion may be the only remaining surgical options.
 - Wrist arthroplasty provides motion at the expense of strength and is considered only in select patients with low-demand wrists or who have fusion of the contralateral wrist. Patients with OA tend to fit this profile, as opposed to those with OA.
 - Total wrist fusion is the ultimate salvage option for all types of wrist arthritis, achieving both pain relief and strength.

TECHNIQUES

■ Distal Interphalangeal Joint Arthrodesis

- The distal interphalangeal joint (DIPJ) is exposed dorsally with a T-shaped incision (**TECH FIG 1A**).
- The extensor tendon is transversely divided, leaving a 5-mm distal stump for later repair.
- The radial and ulnar collateral ligaments are divided, allowing the joint to hinge open.
- Joint debridement is performed using a small rongeur, removing inflamed capsule, ganglions, osteophytes, and residual cartilage.
- A rongeur is used to fashion a concave “trough” at the base of the distal phalanx and a convex “crest” at the head of the middle phalanx until the surfaces align (**TECH FIG 1B**).
- With the joint reduced and compressed at 5 to 10 degrees of flexion, a K-wire is driven through the joint from distal to proximal in a retrograde fashion.
 - A second K-wire is inserted to prevent rotation.
 - The angle is checked with fluoroscopy.
 - A third K-wire may be inserted for further stabilization.
- The extensor tendon is then repaired with a 5-0 absorbable suture, and the skin is closed with interrupted nonabsorbable suture (**TECH FIG 1C**).
 - Soft bulky dressings are applied.
 - The fused joint is supported in a splint for about 6 to 8 weeks until radiographs show bony union (**TECH FIG 1D,E**).
 - At that point, strengthening exercises may be initiated.

TECH FIG 1 • **A.** Skin incision. **B.** Bur is used to create a crest and trough. **C.** Skin closure with K-wires in place. **D,E.** Postoperative radiographs show K-wires in place, fusing the DIPJs of the index and long fingers.

■ Volar Approach to Proximal Interphalangeal Joint Arthroplasty

Silicone Implant

- Patients who do not want proximal interphalangeal joint (PIPJ) fusion for their osteoarthritic pain may consider silicone PIPJ arthroplasty with the understanding that a limited range of motion of 30 to 60 degrees is expected postoperatively.
- Important prerequisites to PIPJ arthroplasty include good bone quality for implant insertion, supple soft tissue coverage, adequate finger sensibility and blood flow, and normal tendon gliding. The best candidate for surgery is a patient with painful PIPJ motion but good stability and normal tendon function.

- We prefer using silicone over pyrocarbon implants given the lower complication rate and the ability to revise the joint more easily if complications arise.
- A V incision over the volar PIPJ is made (**TECH FIG 2A**).
 - Skin flaps are elevated, identifying and preserving the ulnar and radial neurovascular bundles (**TECH FIG 2B**).
 - The A3 pulley is incised and elevated. The flexor tendons are retracted volarly.
 - The volar plate is then incised proximally to expose the arthritic head of the proximal phalanx (**TECH FIG 2C**).
- The head of the proximal phalanx and the base of middle phalanx are excised with an oscillating saw (**TECH FIG 2D–F**).
- The medullary cavity is broached and reamed (**TECH FIG 2G**).
- An appropriately sized implant is then placed (**TECH FIG 2H**).
- Motion at the joint is checked.
- The volar plate is reattached using 4-0 absorbable braided suture.
- The A3 pulley is repaired.
- After skin closure (**TECH FIG 2I**), the hand is placed in a volar splint.
- The patient is seen in the clinic 3 or 4 days after surgery to initiate gentle active range of motion exercises at the PIPJ.
- Splint protection is maintained for approximately 3 weeks to preserve joint alignment and encourage joint encapsulation for additional stability.

Pyrocarbon Implant

- Steps for PIPJ pyrocarbon arthroplasty through a dorsal incision are shown in **TECH FIG 3**.

TECH FIG 2 • PIPJ silicone arthroplasty—volar approach. **A.** A V incision. **B.** Skin flap elevation. **C.** Exposure of the arthritic head of the proximal phalanx. **D–F.** Excision of head of proximal phalanx and base of middle phalanx with oscillating saw. **G.** The medullary cavity is broached and reamed. **H.** Placement of implant. **I.** Skin closure.

TECH FIG 3 • **A.** Incision. **B,C.** Excision of head of proximal phalanx and base of middle phalanx. **D,E.** Medullary cavity of proximal phalanx is broached. **F,G.** Fluoroscopy. **H,I.** Implant is seated into the medullary cavity. **J,K.** Fluoroscopy.

■ Thumb Metacarpophalangeal Joint Fusion for Osteoarthritis

- Patients with instability and pain at the thumb metacarpophalangeal joint (MCPJ) due to osteoarthritis are candidates for arthrodesis.
- A plate is used to achieve long-lasting joint stability for patient comfort.
- A 4-cm incision over the dorsum of the thumb MCPJ is made (**TECH FIG 4A**).
 - The interval between the extensor pollicis longus (EPL) and the extensor pollicis brevis (EPB) tendons is entered (**TECH FIG 4B**).
 - The joint capsule is incised to expose the joint.
- The articular surfaces are removed with a rongeur.
- A low-profile T-plate is selected and bent to fit the MCPJ with about 30 degrees of flexion.
- As the bony surfaces are compressed, the T-plate is fixed to the plate with screws (**TECH FIG 4C**).
 - Fluoroscopy is used to check hardware placement.
- The capsule is closed with 4-0 absorbable suture, and the skin is closed with 4-0 nonabsorbable suture.
- A thumb spica splint is placed.
- The patient is immobilized for 6 to 8 weeks or until radiographic union occurs (**TECH FIG 4D,E**).
 - At 2 weeks, the patient can start engaging in light activities of daily living while wearing the splint.

TECH FIG 4 • Joint fusion for thumb MCPJ instability. **A.** Skin incision. **B.** Interval between EPL and EPB. **C.** Plate placement. **D.** Radiograph of fused MCPJ (AP view). **E.** Radiograph of fused MCPJ (lateral view).

■ Reconstruction for Thumb Trapeziometacarpal Instability Using Flexor Carpi Radialis: Eaton-Littler Procedure

- The Eaton-Littler procedure is reserved for thumb trapeziometacarpal (TM) instability in the setting of intact articular surfaces.
- A modified Wagner incision is made at the junction of glabrous and nonglabrous skin along the border of the thenar eminence (**TECH FIG 5A**).
 - The radial edge of the thenar musculature at its insertion on the metacarpal is identified and elevated to expose the metacarpal base and trapezium (**TECH FIG 5B**).
 - The dorsal cortex of the metacarpal base is further exposed through the interval between the EPL and EPB.

- Using a small bur, a hole is made at the base of the metacarpal, from dorsal to volar, starting at about 1 cm from the joint in a plane perpendicular to the axis of the thumbnail (**TECH FIG 5C**).
- The exit site should be at the apex of the volar beak of the metacarpal.
- For harvest of the flexor carpi radialis (FCR), short transverse incisions centered over the tendon are made at 2- to 3-cm intervals proximal to the volar wrist crease.
- The FCR sheath is entered through these incisions to isolate the radial half of FCR, which is transected at about 6 cm proximal to the wrist crease and separated longitudinally from the other half of the tendon (**TECH FIG 5D**).
- At the wrist crease, the FCR slip is traced to its insertion at the base of the index metacarpal.
- The free end of the FCR is brought out through the thenar incision (**TECH FIG 5E**).

TECH FIG 5 • Reconstruction for thumb trapeziometacarpal instability using FCR (Eaton-Littler). **A.** Skin incision. **B.** The trapeziometacarpal joint is exposed. **C.** A hole is drilled through first metacarpal base (*arrow*). **D.** Harvest of radial half of FCR. **E.** The FCR slip is traced to its insertion at the base of the index metacarpal and brought out the thenar incisions. **F,G.** The tendon is directed through the hole at the base of the first metacarpal, from volar to dorsal, using a wire-loop tendon passer. **H.** The FCR is passed through the first metacarpal. **I.** Final

reconstruction. **J. Skin closure.**

- Using a wire-loop tendon passer, the tendon is directed through the hole at the base of the thumb metacarpal, from volar to dorsal (**TECH FIG 5F,G**).
- Under direct vision, the joint is reduced and held in extension and abduction, seating the metacarpal well against the trapezium.
- The tendon is pulled taut and sutured to the dorsal periosteum with a 3-0 braided nonabsorbable suture.
- The tendon is then passed around the metacarpal base, deep to EPB and abductor pollicis longus (APL), through a small spit in the intact FCR tendon proximal to its insertion, and finally back across the joint and sutured to the APL tendon (**TECH FIG 5H,I**).
- Additional sutures are placed at the junction through the FCR tendon.
- The thenar musculature is reattached using 3-0 braided absorbable suture.
 - The skin is closed with 4-0 nylon horizontal mattress sutures (**TECH FIG 5J**).
- A thumb spica splint is placed and worn for 4 weeks, at which point gentle active ROM exercises are initiated.
 - At 8 weeks, strengthening exercises are begun.

■ Trapeziectomy and Abductor Pollicis Longus Suspensionplasty

- A trapeziectomy with APL suspensionplasty is our preferred technique for thumb TM (carpometacarpal joint [CMCJ]) arthroplasty, as it is faster and technically easier than the Eaton-Littler procedure yet provides comparable outcomes.⁶
- The first incision is made over anatomic snuffbox and TM joint (**TECH FIG 6A**).
 - The radial sensory nerve branches are identified and retracted. The EPL tendon is found at the ulnar aspect of the anatomic snuffbox.
 - The radial artery is identified in close proximity to the TM joint capsule and is mobilized and retracted inferiorly (**TECH FIG 6B**).
 - The TM joint capsule is incised and sharply elevated to expose the scaphotrapezial joint, the trapezium, and the thumb metacarpal base

(**TECH FIG 6C**).

- The trapezium is cut longitudinally into three pieces using an oscillating saw followed by an osteotome.
 - The pieces are removed with a rongeur (**TECH FIG 6D,E**).
 - Osteophytes and loose bodies embedded in the surrounding soft tissues must also be removed meticulously.
 - Care is taken to avoid injury to the FCR tendon as it passes volar to the trapezium at its proximal radial corner.
- The surface of the trapezoid that articulates with the scaphoid is inspected, and if arthritis is present, a partial proximal trapezoidal resection is performed.
- The second incision is made over the first extensor compartment to identify the musculotendinous junction of the APL, which has multiple slips (**TECH FIG 6F**).
- The most radial slip of APL is divided at this junction (**TECH FIG 6G**), passed under the skin bridge into the thumb incision with a hemostat, and traced to its insertion at the thumb metacarpal base (**TECH FIG 6H**).
- The extensor carpi radialis longus (ECRL) tendon is identified ulnarly where it inserts into the base of the index metacarpal, deep to the EPL tendon.
 - A small incision is made longitudinally in the ECRL tendon (**TECH FIG 6I**).
- The APL tendon is then passed volar to EPL and through the hole in the ECRL into a tendon weave (**TECH FIG 6J**).
- The tension is set such that the thumb metacarpal base is suspended at the level of the index metacarpal base.
- The tendon weave between APL and ECRL is secured using 3-0 braided nonabsorbable horizontal mattress sutures (**TECH FIG 6K,L**).
- The remaining tendon is cut, fashioned into a ball with 4-0 absorbable suture, and placed in the trapeziectomy space (**TECH FIG 6M**).
- The joint capsule is closed with 4-0 braided absorbable suture.
 - The skin is closed with 4-0 absorbable monofilament dermal sutures and a 4-0 absorbable monofilament running subcuticular suture (**TECH FIG 6N,O**).
- A thumb spica splint is placed and worn for 4 weeks.
 - Hand therapy is then initiated for passive and active ROM exercises, with the splint worn between exercises.

- At 6 weeks, light strengthening exercises are begun. At 8 weeks, the splint is weaned and heavy strengthening with grip and pinch exercises is initiated.
- Studies show that patients experience significant improvements in activities of daily living, work, satisfaction, and pain at 1 year postoperatively.

TECH FIG 6 • Trapeziectomy and APL suspensionplasty. **A.** First skin incision. **B.** Radial artery is preserved. **C.** Trapezium is exposed. **D.** A rongeur is used to remove the trapezium. **E.** Trapezium has been removed. **F.** APL is identified via second incision. **G.** The radial slip of APL is divided at the musculotendinous junction. **H.** The slip of APL is brought into the thumb incision and traced to its insertion on the thumb metacarpal base. **I.** A small incision is made in the ECRL tendon. **J,K.** The slip of APL is passed volar to EPB and EPL and through the hole in the ECRL into a tendon weave. **L.** Completed APL tendon weave with ECRL. **M.** The excess APL

tendon is cut, sutured into a ball, and inserted into the trapeziectomy space. **N.** Skin closure. **O.** Postoperative x-ray.

■ Arthrodesis of the Thumb TM Joint (Thumb CMCJ Arthrodesis)

- Osteoarthritis of the thumb TM joint (ie, CMCJ) can be addressed with joint fusion, particularly in manual laborers who require greater stability than can be achieved with trapeziectomy and ligament reconstruction.
 - Arthrodesis is also indicated in patients with substantial joint laxity and deformity. In the past, nonunion rate is high using the traditional plating system.
 - We have applied the locking plate and screw design for this joint to provide even more rigid fixation that may enhance fusion.
 - Using locking system is the preferred approach to fuse the thumb CMCJ.
- A 4- to 6-cm dorsal longitudinal incision is made over the TM joint at the base of the thumb metacarpal (**TECH FIG 7A**).
 - The interval between the EPL and EBP tendons is entered, exposing the joint capsule. Care is taken to preserve and retract the radial artery.
 - The joint capsule and periosteum are incised, and periosteal flaps are elevated off the trapezium and metacarpal (**TECH FIG 7B,C**).
- Using a combination of rongeur and osteotome, the articular cartilage and subchondral bone are resected (**TECH FIG 7D**).
- A 2.3-mm locking T-plate is selected and positioned with the T-portion centered on the trapezium and the longitudinal portion centered along metacarpal.
 - Screws are applied with the joint in compression (**TECH FIG 7E**).
 - Plate position is confirmed with fluoroscopy.
 - If any bony gaps exist, cadaveric bone graft is applied.
- The periosteal flaps and joint capsule are closed over the plate using 4-0 absorbable braided suture (**TECH FIG 7F**).
 - After skin closure, a thumb spica splint is placed.
- The patient is immobilized in a thumb spica splint for 6 weeks to allow for bony fusion, after which gentle active ROM exercises are initiated (**TECH**

FIG 7G-I).

TECH FIG 7 • Thumb CMC arthrodesis. **A.** Incision. **B,C.** Radial artery retracted and thumb CMC joint identified. **D.** Chevron-type osteotomy made through base of metacarpal and trapezium. **E.** Thumb CMC fusion with Synthes locking T-plate. **F.** Interval between EPB and EPL closed over plate. **G–I.** Six weeks postoperative x-rays. **J–L.** Results 6 weeks postoperatively.

■ Darrach Procedure for Distal Radioulnar Joint Arthritis

- A dorsal incision is made longitudinally over the distal ulna, just proximal to the extensor retinaculum, taking care to preserve the dorsal ulnar sensory nerve (**TECH FIG 8A**).
 - The interval between the extensor carpi ulnaris (ECU) and extensor digiti minimi (EDM) is entered (**TECH FIG 8B**).
 - The periosteum is incised, and radial and ulnar periosteal flaps are raised.
- An oscillating saw is used to resect 2 cm of distal ulna at a 45-degree angle, such that the long end of the oblique cut is in the ulnar border to minimize impingement against the radius.
- The loose ulnar head is sharply excised from its soft tissue attachments (**TECH FIG 8C**).
 - Sharp edges of bone and synovitis within the sigmoid notch are removed with a rongeur.
- Ulnar stump stability is then assessed.
 - If stable, the tourniquet is release, and hemostasis is achieved with cautery.
 - If unstable, an ECU tenodesis is performed.
- Then, with the wrist fully supinated, the dorsal wrist capsule is imbricated with 2-0 braided nonabsorbable horizontal mattress sutures, ensuring that the ulnar is not dorsally prominent in this position.
- The skin is closed with 3-0 absorbable monofilament dermal sutures and a 4-0 nonabsorbable (**TECH FIG 8D**).
- A sugar-tong splint is applied with the forearm fully supinated for 4 weeks, keeping the fingers free for ROM.
 - Gentle active ROM is started at 4 weeks, but if an ulna-stabilizing procedure has been performed, pronation and supination are delayed until 6 weeks (**TECH FIG 8E**).
 - Full activities may be resumed as tolerated at 6 to 8 weeks.

TECH FIG 8 • Darrach procedure. **A.** Skin incision. **B.** Interval between ECU and EDM is entered. **C.** Excised ulnar head (*arrow*). **D.** Skin closure. **E.** Postoperative x-ray.

■ Hemiresection Arthroplasty of the Distal Ulna

- We prefer hemiresection ulnar arthroplasty over the Darrach procedure for patients with wrist pain due to distal radioulnar joint (DRUJ) osteoarthritis, as it is associated with less postoperative wrist instability⁷ and better wrist range of motion, grip strength, and pain relief.⁸
 - In this procedure, the ulnar attachments of the TFCC (triangular fibrocartilage complex) are preserved.
 - Resection of the radial and dorsal margins of the distal ulna is performed such that the resected bone corresponds with the articular surface of the

sigmoid notch.

- This “matched resection” is performed to prevent radioulnar impingement during forearm rotation.⁹
- The distal ulna is exposed in a similar manner as for the Darrach procedure (see above for details) while maintaining the ulnar TFCC (**TECH FIG 9A–C**).
- Using a miniature C-arm, a Freer is used to delineate the dorsal radial cut of the distal ulna to match the curvature of the sigmoid notch.
- An oscillating saw is used to remove this portion of the ulna (**TECH FIG 9D–F**).
- Pronation and supination are checked to ensure no impingement of the distal ulna on the radius.
- The dorsal capsular sheath over the ulna is imbricated to further stabilize the distal ulna using buried 2-0 nonabsorbable braided horizontal mattress sutures.
- After skin closure (**TECH FIG 9G,H**), the extremity is splinted with the forearm in supination.
- The postoperative supination splint is maintained for approximately 4 weeks to stabilize the DRUJ.
 - After 4 weeks, gentle pronation and supination exercises are initiated.

TECH FIG 9 • Hemiresection ulnar arthroplasty. **A.** Incision. **B.** Sheath incision. **C.** Exposure of arthritic distal ulna. **D–F.** Freer and oscillating saw is used to remove distal ulna. **G.** Fluoroscopy. **H.** Skin closure.

■ Total Wrist Fusion

- A dorsal midline incision is made, centered at the radiocarpal joint and

extending from the third metacarpal neck to about 5 cm proximal to Lister tubercle (**TECH FIG 10A**).

- The skin flaps are elevated, taking care to preserve the cutaneous nerves.
- The third extensor compartment is entered, and the EPL tendon is transposed.
- The extensor retinaculum is incised, exposing the second through fifth extensor compartments.
- The posterior interosseous nerve (PIN) is identified on the floor of the fourth compartment and excised.
- The dorsal wrist capsule is incised along the dorsal intercarpal and dorsal radiocarpal ligaments, creating a radially based capsular flap and elevating it off the dorsal triquetrum.

TECH FIG 10 • Total wrist fusion. **A.** Skin incision. **B.** Dorsal wrist anatomy showing areas decorticated and removed of cartilage in preparation for fusion: third CMC, radioscaphoid joint, radiolunate joint,

scaphocapitate joint, lunocapitate joint. **C.** Fusion plate placed. **D.** Wrist capsule and extensor retinaculum are repaired. **E.** Skin closure. **F,G.** PA and lateral postoperative x-rays.

- The dorsal radius, carpus, and third metacarpal are then exposed via a subperiosteal dissection and further decorticated with an osteotome.
- Lister tubercle is removed to allow the plate to seat well on the radius.
- The articular cartilage and subchondral bone are removed from the radioscaphoid, radiolunate, scaphocapitate, lunocapitate, and third carpometacarpal joints to prepare them for fusion (**TECH FIG 10B**).
 - Care is taken to maintain carpal height by avoiding over-resection of bone.
- Soft tissues are released as needed to permit joint reduction and alignment at about 10 degrees of extension and slight ulnar deviation.
- The surface of the radius is contoured to fit the curvature of the fusion plate.
- The prepared joint spaces are filled with the bone graft.
 - For healthy patients, we use cadaveric bone graft, whereas for smokers or those at risk for wound healing delay, we prefer using bone autografts from the iliac crest.
- The fusion plate is applied, spanning from the distal radius to the third metacarpal.
 - A screw affixing the plate to the third metacarpal is placed in a neutral, unrotated position.
- With the wrist joint compressed, the plate is further affixed to the radius (**TECH FIG 10C**).
 - The remaining screws are placed.
 - Hardware placement is checked with fluoroscopy.
 - Full forearm rotation and passive digital ROM should be intact.
- Once the plate is secured, additional bone graft is packed into the prepared joint spaces.
- The wrist capsule is closed over the plate.
 - The extensor retinaculum is repaired, leaving the EPL transposed over the retinaculum.
 - The skin is closed with absorbable monofilament dermal and subcuticular running sutures (**TECH FIG 10E–G**), and a bulky volar wrist splint is

applied.

- Typically, at 2 weeks postoperatively, a removable wrist splint is provided for full-time wear and may be removed transiently for personal hygiene.
- The splint is worn for 3 months.
- However, if the fixation is tenuous or patient compliance is questionable, a postoperative cast should be placed.
- Digital ROM and edema control are encouraged throughout this time frame.
- Upon surgical recovery, patients should expect pain relief, full digital ROM, full forearm rotation, and the ability to complete most activities of daily living.

PEARLS AND PITFALLS

DIPJ ARTHRODESIS

Exposure

- Avoid injury to the germinal matrix of the nail fold.
- If the joint deformity is fixed, adequate soft tissue release must be performed to reduce the joint in an optimal position. This includes release of the volar plate, if necessary.

Shaping the bone

- As an alternative to burring a “crest-and-trough” configuration, the bone ends can be cut with the distal bone at 0 degrees and the proximal bone at the desired angle of fusion.
- Avoid excessive bony removal to preserve length and retain good quality bone for healing.

Other techniques for DIPJ arthrodesis

- The two other most commonly reported techniques for DIPJ fusion include the use of headless compression screws or interosseous cerclage wires. Although evidence is insufficient to support any particular technique, the technique with the least reported complications is K-wiring.¹⁰
- If a headless compression screw is placed across the joint, it should be aimed from proximal to distal and slightly palmar to avoid the nail matrix.

SILICONE PIPJ ARTHROPLASTY

Preoperative assessment of collateral

- The collateral ligaments of the PIPJ must be assessed for stability preoperatively.

ligaments	■ If deficient, the patient may require collateral ligament reconstruction at the time of surgery or may eliminate patient candidacy for arthroplasty.
Finger selection	■ Avoid the use of silicone implants at the index and long finger PIPJs, particularly in young, active patients, because repetitive stresses on the radial collateral ligaments during key or chuck pinch can result early implant failure.
Alternative implants: pyrocarbon	■ Pyrocarbon, or pyrolytic carbon, implants have enhanced lateral stability that makes implantation into the index finger PIPJ more attractive compared to silicone. ■ However, pyrocarbon implants have fallen out of favor due to complication rates as high as 30%. ■ If performed, pyrocarbon PIPJ arthroplasty can be done through a lateral or dorsal approach (see TECH FIG 3A–K).

THUMB MCPJ FUSION

Techniques for thumb MCPJ fusion	■ Thumb MCPJ fusion can be accomplished with a variety of techniques, depending on surgeon preference: ■ Tension band wiring ■ Crossed K-wire fixation ■ Plate fixation ■ Intramedullary implant placement ■ For patients with RA, K-wire placement is the author's preferred technique given that thumb MCPJ fusion is often combined with a number of other procedures dealing with the rheumatoid hand.
Angle of fusion	■ The fused position of the thumb MCPJ should be at about 5–15 degrees of flexion for optimal functionality. ■ Slightly more flexion at 20–40 degrees may be considered in patients at risk for developing/worsening OA at the thumb CM CJ.

THUMB TM LIGAMENT RECONSTRUCTION WITH FCR

Anatomy of the thumb CM CJ	■ The thumb CM CJ is the articulation between the trapezium and the thumb metacarpal. It is also known as the trapeziometacarpal (TM) joint. ■ It is a biconcave saddle-shaped joint that permits thumb flexion, extension, abduction, adduction, and opposition. ■ The volar beak ligament is the primary stabilizer of the thumb CM CJ. It extends from the ulnar base of the thumb metacarpal onto the trapezium.
-----------------------------------	--

Harvest of FCR	■ The radial half of the FCR tendon is harvested. ■ The radial artery and sensory nerve branches must be identified and protected. ■ Injury to the palmar cutaneous branch of the median nerve, which lies 1 mm ulnar to the FCR tendon, must be avoided. ■ Care should be taken to separate the radial half of FCR from the ulnar half as to avoid accidental transection. Scissors should not be used to slide down the tendon and instead to make deliberate cuts from proximal to distal.
Postoperative course	■ Thumb CMCJ stiffness is expected for 4–6 wk after surgery but can last up to 4 mo. ■ Patients can expect near-complete pain relief and minimal progression of degenerative arthritis at the CMCJ provided that the surgery is performed prior to onset of articular cartilage destruction.
TRAPEZIECTOMY WITH APL SUSPENSIONPLASTY	
MCPJ laxity	■ Remember to assess the patient's thumb MCPJ for hyperextensibility during pinch. ■ If laxity greater than 30–40 degrees is present and unaddressed, ligament reconstruction will be stressed by obligatory metacarpal adduction. ■ Hyperextensibility at the MCPJ can be addressed with joint capsulodesis, volar plate advancement, or fusion. We advocate MCPJ fusion in these cases because soft tissue imbrication tends to attenuate over time, whereas fusion has a more predictable outcome.
Carpal tunnel syndrome	■ Up to 43% of patients with TM joint arthritis have concomitant carpal tunnel syndrome. If present, a carpal tunnel release should be performed as well.
Eaton classification	■ The Eaton classification of TM osteoarthritis (see Table 1), which is based on radiographic findings, often does not correlate with patient symptoms.
Radiographs	■ A stress view of the TM joint is useful to assess joint space loss and subluxation in patients with symptomatic joint laxity (Eaton stage I). This is obtained by pressing the thumb tips together with a 30-degree posteroanterior view.
Arthritic involvement of the trapezoid	■ If degenerative changes are present between the trapezoid and the scaphoid, concomitant partial resection of the trapezoid is recommended. This is done to ensure that no contact between

	the scaphoid and trapezoid occurs with axial loading. ■ Traction on the index and long fingers after trapeziectomy will allow visualization and assessment of the scaphotrapezoid joint.
Exposure of the trapezium	■ A dorsal approach provides easy access to the trapezium. ■ Identify and protect these four structures: ■ Radial sensory nerve branches ■ Extensor pollicis longus (EPL) tendon ■ APL tendon ■ Radial artery (located deep to the fatty tissue between EPL ulnarly and APL radially) ■ Thumb traction can help facilitate exposure of the trapezium.

THUMB TM JOINT ARTHRODESIS

Anatomy	■ One must protect the radial sensory nerve during exposure of the thumb TM joint. ■ The radial artery must be protected in the interval between the EPL and EPB tendons where it lies deep to the subcutaneous fat.
Plate selection	■ A 2.3-mm locking T-plate is preferred, with the T-portion centered on the trapezium. ■ Utilization of a locking plate is important in the setting of poor bone stock. The trapezium is often devoid of strong cortical bone necessary to secure traditional screws and plates.
Functional thumb position	■ The thumb should be fixed at 30–40 degrees of palmar abduction, 15–20 degrees of extension, and 15 degrees of pronation. ■ This functional position facilitates tip-to-tip pinch.

DARRACH PROCEDURE

Indications	■ Post-traumatic DRUJ arthritis, rheumatoid arthritis, or osteoarthritis without pre-existing radiocarpal instability in patients who are older and sedentary ■ Caput ulna syndrome with TFCC destruction and painful pronation-supination of the DRUJ ■ Preferred in patients with no ulnar translation of carpus who are at low risk of translation in the future ■ Can be performed concomitantly with partial or total wrist fusion in setting of radiocarpal instability ■ Notably, we tend to avoid the Darrach procedure in osteoarthritis, as it weakens the wrist. We prefer hemiresection
--------------------	---

	arthroplasty of the distal ulna (see Technique no. 8).
Caput ulna syndrome	■ Combination of ulnar head dorsal dislocation, ECU volar subluxation, and carpal supination seen in patients with rheumatoid arthritis ■ The fifth extensor compartment (containing EDM) crosses the ulnar head.
Extent of ulnar head resection	■ The pronator quadratus (PQ) is a dynamic stabilizer of the distal ulna, originating at the distal radius and inserting on the distal ulna. ■ Ulnar head excision should be performed at the level of the sigmoid notch in order to preserve the ulnar attachments of the PQ.
Ulna-stabilizing procedure	■ Prior to closing the wrist capsule, the distal ulna stump is tested for stability with pronation-supination. ■ If unstable, an ulnar stabilizing procedure is indicated (ECU tenodesis): ■ A hole in the dorsal cortex of the distal ulnar stump is drilled with a 3-mm bur. ■ The distally based ulnar half of the ECU is harvested and brought from inside the ulnar canal and out the hole dorsally. ■ The ECU is then sutured to itself with the ulnar stump reduced palmarly and wrist in 15-degrees of extension and 15-degrees of ulnar deviation. ■ The wrist capsule is then closed as described in the text.
HEMIRESECTION ARTHROPLASTY OF THE DISTAL ULNA	
Relative contraindications	■ Hemiresection ulnar arthroplasty should be considered with caution in younger patients because it may lead to loss of support for the ulnar carpus over time. ■ Ulnar-positive variance is a relative contraindication for hemiresection ulnar arthroplasty because it increases the risk of impingement between the ulnar styloid and triquetrum. ■ Other contraindications to hemiresection ulnar arthroplasty include pre-existing ulnar carpal translation (may exacerbate the ulnar translation) and irreparable damage to the TFCC (no benefit over a Darrach procedure).
Technical points	■ Avoid excessive resection of the ulnar head. ■ Preserve the foveal attachments of the TFCC. ■ If necessary, debride the TFCC. ■ Consider ulnar shortening if positive variance is present.

TOTAL WRIST FUSION

Indications	■ Painful wrist with limited ROM due to osteoarthritis, inflammatory arthritis, and post-traumatic arthritis ■ Multiple joint involvement ■ Failed partial wrist fusions or soft tissue reconstructions ■ Carpal instability patterns (eg, SLAC/SNAC arthritis) ■ Contraindications for joint arthroplasty or failed arthroplasty ■ Desire for a one-stage definitive treatment.
Dorsal wrist capsule	■ The wrist capsule can be elevated as a radially based flap (as described in the text) or via a straight midline longitudinal incision. ■ A thick capsular flap should be maintained for good coverage of the fusion plate. ■ The ECRL and ECRB tendons can be released from their metacarpal insertions and used to augment soft tissue coverage of the hardware.
The fusion mass	■ Bony fusion involves the radius, scaphoid, capitate, lunate, and third metacarpal bones. ■ Not included in the fusion mass are the ulnar joints (lunotriquetral and triquetrohamate joints).
Proximal row carpectomy (PRC)	■ Performing a PRC may help to facilitate joint alignment before fusion, particularly in cases of chronic and severe carpal deformity.
Fusion plate	■ A dynamic compression plate is used for wrist fusion and must be contoured appropriately to allow for 10 degrees of wrist extension and slight ulnar deviation. ■ In patients with poor bone stock, locking screw fixation can be used.
Postoperative splinting	■ A supportive wrist splint is applied at the end of the case. ■ Avoid MCPJ extension in the splint, which may result in intrinsic tightness and loss of digital ROM.

COMPLICATIONS

- Inadequate pain relief
- Wound healing delay
- Nonunion
- Hardware failure

- Failure of reconstruction
- Infection
- Need for further surgery

Section VIII: Nerve Conditions

26

CHAPTER Carpal Tunnel Release

Angelo B. Lipira and Jason H. Ko

DEFINITION

- Compression of the median nerve at the level of the wrist is the most common compression neuropathy, with a prevalence of 1% to 3%.¹
- Patients present with numbness or paresthesias in the distribution of the median nerve (thumb, index finger, middle finger, radial half of ring finger).
- Long-standing carpal tunnel syndrome (CTS) can result in weakness and atrophy of the thenar musculature; sensory fibers are preferentially affected earlier in the process.
- CTS is diagnosed clinically. It is often confirmed with electrodiagnostic studies, which can also indicate the severity of nerve injury.

ANATOMY

- The median nerve provides sensation to the thumb, index finger, middle finger, and radial half of the ring finger, as well as the skin of the thenar eminence via the palmar cutaneous branch. It provides motor function to the thenar musculature via the recurrent motor branch and radial two lumbricals via the proper (first lumbrical) and common (second lumbrical) digital nerves (**FIG 1A**).
- The carpal tunnel is an anatomic space bounded by the transverse carpal ligament (TCL) volarly; the hamate, triquetrum, and pisiform ulnarly; the scaphoid and trapezium radially; and the lunate and capitate dorsally (**FIG 1B**).
- The carpal tunnel contains the median nerve and nine flexor tendons (four flexor digitorum superficialis [FDS], four flexor digitorum profundus, and

flexor pollicis longus).

- The recurrent motor branch innervates the abductor pollicis brevis, opponens pollicis, and superficial head of flexor pollicis brevis. Most commonly, it arises from the median nerve distal to the TCL (extraligamentous, 46%) but may be subligamentous (31%) or transligamentous (23%). Variants that arise from the ulnar aspect of the median nerve and cross over the TCL are at highest risk of injury, particularly in endoscopic techniques.²
- The palmar cutaneous branch usually branches from the radial aspect of the median nerve 5 to 8 cm proximal to the wrist crease and travels distally between the flexor carpi radialis (FCR) and palmaris longus.
- Therefore, thenar sensation is typically preserved in CTS.
- However, the palmar cutaneous branch can also show variation, including a variant where it branches from the ulnar aspect of the median nerve.² The branch becomes superficial at the wrist level and is vulnerable during incisions.

PATHOGENESIS

- Increased pressures within the carpal tunnel lead to vascular congestion, edema, and ischemia of the median nerve.
- Demyelination occurs first, followed by axonal degeneration in more severe cases. Sensory nerve fibers are affected earlier than motor fibers.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient history
 - Patients will often report numbness of the entire hand, rather than localizing it to the median nerve distribution.³
 - Classically, patients will report being awakened by paresthesias and pain, as symptoms often worsen at night because during sleep, the wrist relaxes and is often flexed for prolonged periods of time, leading to elevated pressure in the carpal tunnel. Furthermore, many will sleep with their hands and wrists under the head, which also contributes to nerve compression.
 - They may report weakness or clumsiness in more advanced presentations with motor weakness.
 - Investigate associated conditions including diabetes mellitus, rheumatoid arthritis, obesity, gout, hypothyroidism, and pregnancy.^{1,4}
 - Take a good occupational history, identifying predisposing and repetitive tasks that may contribute to increased carpal tunnel pressure.

- Inquire about past therapies including splinting and steroid injections.
- Physical examination
 - Inspect the hand, looking for atrophy of the thenar musculature and differences in temperature and sweat patterns in the median nerve distribution.
 - Test and document two-point discrimination (static and dynamic) on both the radial and ulnar aspects of all digits (normal values: static less than 6 mm, moving 2–3 mm).
 - Provocative maneuvers are used in an attempt to reproduce the patient's symptoms⁴:
 - Phalen test: The wrists are held in a flexed position for up to 1 minute. Record the time it takes to precipitate their usual symptoms.
 - Tinel sign: The examiner percusses over the median nerve at the wrist. If tingling paresthesias are elicited in the fingers, the test is considered positive.
 - Durkan carpal compression test: Direct pressure is applied over the carpal tunnel with the examiner's thumb. Apply just enough pressure to blanch the overlying skin. Record the time it takes to precipitate their usual symptoms.⁵

FIG 1 • A. Structures at risk during carpal tunnel release include the palmar cutaneous sensory branch, typically arising ulnarly just proximal to the transverse carpal ligament (TCL), and the recurrent motor branch, typically arising radially just distal to the TCL. **B.** Anatomic boundaries of the carpal tunnel include the TCL volarly; hamate, triquetrum, and pisiform ulnarly; lunate and capitate dorsally; and the scaphoid and trapezium radially. The carpal tunnel contains nine flexor tendons—four flexor digitorum superficialis, four flexor digitorum profundus, and flexor pollicis longus—and the median nerve.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The diagnosis of CTS is usually made clinically, and electrodiagnostic studies are frequently employed to confirm the diagnosis and rate the severity.
- Imaging is not routinely performed for CTS but may be indicated if there is suspicion of a mass lesion or other rarer presentations.
- Electrodiagnostic studies focus on assessing the conduction velocities and amplitude of the median nerve across the wrist. The ulnar and radial nerve are also often evaluated to compare values in a nerve outside the carpal tunnel and rule out effects of temperature, polyneuropathy, and other factors.
- Nerve conduction studies may demonstrate increased sensory or motor latency (demyelination) and decreased sensory and/or motor amplitude (loss of axons).⁴ Sensory latencies are compared to an unaffected nerve (ulnar or radial) and are generally considered abnormal if the difference exceeds 0.3 to 0.5 ms. Motor conduction is assessed by stimulating the median nerve at the wrist and measuring at the abductor pollicis brevis. Latency of over 4.5 ms is generally considered abnormal.⁶
- The combined sensory index (CSI) is a useful composite value that is obtained by measuring the difference in latency between the thumb, palm, and ring fingers and the ulnar or radial nerve and summing these three values together. A CSI of 1 ms or more is considered abnormal.⁷ Higher CSIs have been associated with greater frequency of symptom resolution following carpal

tunnel release (CTR).⁶

- There is evidence that preoperative electrodiagnostic studies may increase costs and delay time to surgical treatment. Although the American Association of Orthopaedic Surgeons (AAOS), in a prior proactive guideline, recommended electrodiagnostic studies if surgery is being considered, a substantial portion of hand surgeons do not routinely obtain them.⁸

DIFFERENTIAL DIAGNOSIS

- Proximal median nerve lesion (eg, compression from pronator teres, FDS arch, or an accessory muscle such as Gantzer muscle)
- Polyneuropathy
- Central nervous system lesion (tumor, CVA, multiple sclerosis)
- Arthritis

NONOPERATIVE MANAGEMENT

- Nonoperative therapies for CTS include avoidance of provocative maneuvers, wrist immobilization (splinting), nonsteroidal anti-inflammatory drugs (NSAIDs), and corticosteroid injection.
- Wrist braces should hold the wrist in a neutral position. Wrist flexion or extension increases pressure in the carpal tunnel. However, the active position of the wrist is 30 degrees of extension, so neutral splints can make tasks more difficult.
- Although corticosteroid injection leads to transient relief in many patients, the majority will recur within 1 year.⁹ Some surgeons believe that relief with steroid injection is predictive of relief with operative CTR and thus holds diagnostic value.
- Dexamethasone is the preferred corticosteroid, as it appears to be less deleterious than hydrocortisone or triamcinolone if inadvertently injected into the nerve substance.¹⁰

SURGICAL MANAGEMENT

- CTR is commonly performed using both open and endoscopic techniques.
- There is currently no consensus supporting the superiority of one technique over the other.

Preoperative Planning

- Preoperative planning is based on the patient's history and physical exam, as

well as review of electrodiagnostic studies, if available.

- Considerations include conducting unilateral vs bilateral releases, anesthesia plan (local, regional block, sedation), and special considerations in the case of recurrent CTS (see below).
- A recent study showed that patients undergoing bilateral simultaneous CTR have increased difficulties with certain activities compared with unilateral CTR, but self-care was unaffected, and the differences did not persist past two postoperative days.¹¹
- Open CTR can be performed under local anesthetic block with or without sedation or regional block such as Bier intravenous block (**FIG 2**).
 - General anesthesia is not typically required.
- Endoscopic CTR can be difficult to perform under local anesthetic, as the liquid in the carpal tunnel can obscure visualization, so one of the other anesthetic techniques is recommended.
- In cases of recurrent or persistent CTS following CTR, be sure to rule out other etiologies of symptoms, such as cervical radiculopathy, proximal median nerve or brachial plexus lesions, and polyneuropathy.
 - If the patient has hypersensitivity directly over the carpal tunnel without evidence of palmar cutaneous branch injury, or if the median nerve is found to be adherent to the TCL intraoperatively, we consider the interposition of a hypothenar fat pad flap at the time of reoperation.¹²

Positioning

- The patient is positioned supine on an OR table or stretcher, with the operative extremity on a hand table.
- A well-padded, nonsterile tourniquet is placed on the upper arm prior to prep and drape.
- The surgeon is seated with his or her dominant hand more proximal relative to the operative extremity so that they are working distally down the carpal tunnel.
- A sterile folded towel is placed under the wrist to slightly extend the wrist (15–20 degrees), which moves the median nerve away from the TCL.
- For positioning considerations specific to endoscopic CTR, see section below.

FIG 2 • Typical setup for Bier block anesthesia. Note the intravenous line in the dorsum of the hand and the double tourniquet.

Approach

- Techniques can be broadly divided into open or endoscopic. Open approaches include numerous described incisions, including limited incision and minimally invasive approaches.
- Although numerous variations of incisions for open CTR have been described, most agree that it should be in line with the ring finger, thus slightly ulnar to the axis of the median nerve and less likely to cause injury to the palmar cutaneous branch.
- We prefer a 2- to 3-cm longitudinal curvilinear incision, staying 2 mm ulnar to the thenar crease to avoid the palmar cutaneous branch. The distal extent is well short of Kaplan cardinal line, which identifies the location of the palmar arterial arch (**FIG 3**).
- Endoscopic approaches include single-portal¹³ and two-portal¹⁴ techniques.
 - We prefer the single-portal (Agee) technique, and the proximal incision is typically a 1- to 1.2-cm transverse incision placed in the distal flexion crease of the wrist, just ulnar to the palmaris longus tendon (halfway between FCR and flexor carpi ulnaris [FCU] tendons).

FIG 3 • Incision placement for open carpal tunnel release. It is typically 2 to 3 cm long, in line with the ring finger, and at least 2 mm ulnar to the thenar crease to avoid the palmar cutaneous branch. *Circle* denotes hook of hamate, a palpable landmark. Note incision terminates proximal to Kaplan cardinal line (*dotted line*), which is drawn by extending the ulnar border of the abducted thumb ulnarly and denotes the location of the palmar arterial arch.

TECHNIQUES

■ Open Carpal Tunnel Release

- Mark a 2- to 3-cm longitudinal curvilinear incision 2 mm ulnar to the thenar crease.
- Exsanguinate the arm with an Esmarch bandage, and inflate the tourniquet to 250 mm Hg (or 100 mm Hg over systolic blood pressure).
- Incise full thickness through skin incision with a 15-blade scalpel.
- An assistant retracts the skin with two Senn retractors while dissection is carried down sharply through the subcutaneous tissues until the transverse carpal ligament (TCL) is encountered. During this dissection, be mindful of ulnar variants of the palmar cutaneous branch that may be encountered

(TECH FIG 1A).

- Using a no. 15 blade, carefully incise the TCL, using a controlled “push,” rather than a slicing motion.
- Once the median nerve is visualized, complete as much of the release of the TCL under direct visualization with the use of a scalpel blade.
- Then use tenotomy scissors to spread both superficial and deep to the TCL, being careful to separate the median nerve (which can be quite adherent) from the deep surface of the TCL. Insert one tine of the tenotomy scissors and divide the TCL distally until the palmar fat surrounding the superficial vascular arch of the palm is reached (**TECH FIG 1B,C**).
- Attention should now be turned toward dividing the proximal TCL and contiguous antebrachial fascia. The surgeon should change positions so that he or she is now seated at the end of the hand table for optimal visualization. Extend the skin incision proximally if necessary (**TECH FIG 1D**).
- Again dissect both superficial and deep to the TCL, separating the median nerve from the deep surface of the TCL. Under direct visualization, release the proximal end of the TCL.
- Continue spreading and dissecting proximally, exposing the deep antebrachial fascia. It is important for the surgical assistant to use two Senn retractors to lift away the skin and subcutaneous tissue to expose the antebrachial fascia proximally. Use tenotomy scissors to release the antebrachial fascia proximally for at least 1 cm proximal to the distal wrist crease.
- Consider lifting the flexor tendons in the carpal tunnel using a Ragnell retractor, and inspect for any mass lesions, such as ganglia, within the tunnel.
- Inject bupivacaine (0.25% with epinephrine) locally into the incision.
- Deflate the tourniquet while holding pressure on the incision.
- Attain meticulous hemostasis.
- Close the incision with 4-0 nylon simple interrupted or horizontal mattress sutures.
- Apply a soft, bulky dressing consisting of nonstick gauze, fluffs, and Kerlix or Ace wrap. Allow for immediate postoperative motion.

TECH FIG 1 • Open carpal tunnel release. **A.** A small self-retaining retractor and a Ragnell retractor provide exposure of the TCL. **B.** After bluntly spreading above and below the TCL, it is divided with the tenotomy scissors. **C.** Distal division of the TCL has been completed to the level of the distal palmar fat. **D.** The proximal antebrachial fascia is exposed by bluntly spreading above and below and then divided with the tenotomy scissors.

■ Endoscopic Carpal Tunnel Release

Preparation and Incision

- To avoid fogging of the lens, the lens can be placed in warm water or saline for several minutes prior to use. Otherwise, defogging solution can be applied to the lens immediately prior to use.

- Position the monitor at the distal end of the hand table. Assemble the blade/scope unit and then white-balance the camera (can use a white surgical sponge). Test the camera and endoscopic device blade prior to proceeding. Have defogging solution available on a sponge to defog the lens, if needed. Place a folded OR towel under the wrist to extend it.
- Mark a transverse incision approximately 1 to 1.2 cm in length at the distal transverse wrist crease, slightly ulnar to the palmaris longus (if present) (**TECH FIG 2**).
- Exsanguinate the arm with an Esmarch bandage, and inflate the tourniquet to 250 to 300 mm Hg (or 100 mm Hg over systolic blood pressure).

Accessing the Carpal Tunnel

- Incise the skin with a 15 blade, and use bipolar cautery to coagulate small subcutaneous vessels.

TECH FIG 2 • A,B. Incision marking for endoscopic carpal tunnel release. The palmaris longus tendon (when present) is often palpable when the thumb and small finger are opposed and the wrist flexed. The incision is marked transversely in the distal flexion crease of the wrist, slightly ulnarly translated over palmaris longus (PL, Palmaris longus).

- If excessive fatty tissue is present, perform a direct subcutaneous lipectomy.
- Use tenotomy scissors to release the superficial antebrachial fascia.
- Two Ragnell retractors are then used to bluntly spread through the subfascial tissue to expose the TCL.

- Pick up the TCL with Adson forceps distally (**TECH FIG 3A**), and make a small transverse fasciotomy with a no. 15 blade scalpel until the underlying nerve is visualized.
- Once the fascial incision is large enough to insert the tips of tenotomy scissors, use the scissors to extend the fasciotomy transversely with a single, large spreading motion.
 - Then, make a longitudinal fascial incision along the ulnar aspect of the fasciotomy for about 5 mm to create an L-shaped flap.
- Use a small double-skin hook to lift the L-shaped flap of the proximal TCL (**TECH FIG 3B**).
- With a synovial elevator, using gentle pushing motions (not scraping), clear off the deep surface of the TCL, which helps to effectively push the oft-adherent median nerve away from the TCL.
 - Advance the elevator until it can be passed into the palm and palpated there with your left hand. This should be done in line with the ring finger (**TECH FIG 3C,D**).
- Sequentially introduce two progressively larger sound dilators into the dissected space between the median nerve and the TCL (**TECH FIG 3E,F**).
- Take the light off standby, and again check the blade engagement mechanism and make sure the blade recedes back into the blade sheath upon trigger release.

Inserting and Advancing the Endoscope

- Insert the assembled scope and blade in line with the ring finger.
 - Rotate the blade sheath slightly ulnarly while introducing it beneath the L-shaped fascial flap.
- If using hot water to eliminate fogging of the camera, after placing the blade/endoscope unit deep to the TCL, remove the scope from the sheath and immerse it in hot water. Rub it dry with a 4 × 4 Raytec gauze. Turn the room lights down, and reintroduce the scope into the blade unit.

TECH FIG 3 • Accessing the carpal tunnel. **A.** Once exposed, the TCL is grasped with forceps, and a small transverse nick is made with a no. 15 blade. Next, a blunt spread of the tenotomies under the TCL clears the median nerve from its undersurface, and the incision is extended longitudinally along the ulnar aspect to create an L-shaped flap. **B.** A small double hook is used to retract the L-shaped flap. **C.** From top down: synovial elevator, small dilator, large dilator; to be used in that sequence. **D.** Using the synovial elevator, gentle pushing motions (not pulling) clear the synovium from the deep surface of the TCL. **E,F.** The smaller dilator is then passed through the carpal tunnel, followed by the larger dilator. The tunnel is now

prepared for insertion of the endoscopic device.

TECH FIG 4 • Endoscopic view showing the TCL forming the roof of the carpal tunnel, predivision. Note that it has been cleared of adherent synovium. Also note the palmar fat visible at the distal extent of the tunnel.

- If using defogging solution, this step can be skipped.
- Advance the scope until the distal aspect of the TCL is visualized, usually corresponding to the 3.5-cm measurement on the sheath.
- While watching the video monitor, the surgeon's hand that is not controlling the scope can be used to push on the palm repeatedly to determine where the distal edge of the TCL is located, since the tight TCL will minimize motion of the tissues even upon deep palpation.
 - However, the tissue distal to the TCL will “bounce” more easily with palpation (**TECH FIG 4**).

Releasing the Carpel Tunnel and Completion

- Ensure that the hand is completely flat against the towel (with the thenar

eminence firmly pushed down by the assistant) to tighten the TCL while moving the nerve as far away from the blade as possible.

- Engage the blade and slowly pull the scope proximally to cut the distal end of the TCL, stopping at approximately halfway (**TECH FIG 5A**).
 - Disengage the blade and readvance the scope to visualize the distal aspect of the TCL, ensuring no uncut bands remain distally. Any residual fibers can be cut at this time (**TECH FIG 5B**).
- The scope is pulled proximally again, and the blade is engaged again just before reaching the proximal, uncut edge of the TCL.
 - Continue pulling the device proximally to divide the remainder of the ligament while applying pressure to the palm with the hand not controlling the scope, which “pushes” the TCL into closer approximation with the blade.
- The scope can be reintroduced to visualize any residual fibers of TCL, though after release of the TCL, the superficial fat can obscure the view seen on the monitor.
- Remove the scope.
- Introduce closed tenotomy scissors under the cut TCL (superficial to the nerve).
 - Using a bimanual palpation technique, the tips of the tenotomy scissors can be gently run along the deep surface of the palm to determine if any fibers of TCL remain while the surgeon’s other hand follows the tips of the tenotomy scissors on the surface of the palm.
- Attention should now be turned toward dividing the proximal antebrachial fascia, which is a very important part of the endoscopic carpal tunnel release.
 - The surgeon should change positions to be seated at the end of the hand table for optimal visualization.
- Retract the skin and fat above the proximal superficial and deep antebrachial fascia using a Ragnell retractor, and divide the antebrachial fascia proximally with tenotomy scissors for approximately 2 cm.
- The incision can be approximated with 4-0 nylon suture in a simple or horizontal mattress fashion.
- Infiltrate a 0.25% bupivacaine with epinephrine into the incision, along with the area of the released TCL and antebrachial fascia.
- Apply a soft dressing of fluffs and a 4-in. Kling wrap.
- Apply firm pressure at the incision site through the dressing while deflating

the tourniquet.

TECH FIG 5 • A. With the blade engaged, division begins at the distal extent of the TCL by slowly withdrawing the device. **B.** Following the initial pass of the blade, much of the TCL has been divided, exposing the overlying pink palmar fascia. Note the band of intact TCL that must be divided with a second pass.

■ Hypothenar Fat Flap

- In cases of recurrent or recalcitrant carpal tunnel syndrome (CTS), excessive scar formation may contribute to entrapment of the nerve. The hypothenar fat flap is a technique to interpose healthy, vascularized tissue over the nerve to prevent recurrence from aggressive scar formation.
- Exsanguinate the arm with an Esmarch bandage, and inflate the tourniquet to 250 mm Hg (or 100 mm Hg over systolic blood pressure).
- Make a linear incision just radial to the hypothenar eminence, and carry dissection down to the carpal tunnel to identify the median nerve.
 - Typically, the hypothenar fat flap is used for the treatment of recalcitrant CTS, so the incision can be made through the previous surgical scar (**TECH FIG 6A**).
- Perform external neurolysis of the median nerve.

- Using sharp dissection, develop a subdermal plane over the adipose tissue of the hypothenar region, being cautious not to make the cutaneous flap too thin. Carry this dissection to the dermal insertion of the palmaris brevis¹² (**TECH FIG 6B**).
- Perform deep dissection under the fat pad, directly over the hypothenar musculature, until the ulnar nerve and artery are visualized.
- Check if the flap has been sufficiently mobilized to be advanced to the radial wall of the carpal tunnel (**TECH FIG 6C,D**).
- If not, carefully perform additional dissection, being careful to preserve the vascular pedicles of the flap and the ulnar neurovascular structures.
- Retract the carpal tunnel contents ulnarly, and place the hypothenar fat pad flap volar to the median nerve and deep to the radial leaf of the TCL. Place horizontal mattress sutures through the flap and into the radial wall of the carpal tunnel. Tag these sutures and sequentially tie them once all have been placed.
- Irrigate the wound and deflate the tourniquet. Achieve meticulous hemostasis.
- Approximate the skin using 4-0 nylon suture in a simple interrupted or horizontal mattress fashion. Apply dressings as described above.

TECH FIG 6 • Hypothenar fat pad flap. **A.** The carpal tunnel has been released, the median nerve has been neurolysed, and a subdermal plane has been developed over the adipose of the hypothenar region. **B.** The hypothenar fat pad flap must be mobilized sufficiently to reach the radial wall of the carpal tunnel. The subdermal plane is developed to the dermal insertion of palmaris brevis, and the deep dissection is carried out just over the musculature until the ulnar neurovascular bundle is visualized. **C.** The elevated hypothenar fat pad flap, prior to inset.

PEARLS AND PITFALLS

Incomplete release	■ Be sure to adequately release the distal TCL in the palm to the level of the palmar fat pad, and the antebrachial fascia for 1–2 cm in the forearm. In endoscopic CTR, check for bands of undivided TCL by palpating with closed tenotomy scissors.
Palmar cutaneous branch injury	■ Make incision ulnar to axis of ring finger. Look out for ulnar cutaneous branch variant.
Recurrent motor branch injury	■ Subligamentous and transligamentous variants are at increased risk specifically with endoscopic CTR. Rare variant that exits median nerve ulnarly and curves distally around TCL is highest risk. ²
Superficial palmar arch injury	■ Located 2–26 mm from the distal edge of TCL, contained in palmar fat pad ¹⁵
Radially located ulnar artery	■ In some patients, the ulnar artery is located radial to the hook of hamate, making it vulnerable during CTR. ¹⁵
Visualization on endoscopy	■ Watch the monitor closely at all times while the endoscopic device is entering, exiting, or within the carpal tunnel.
Anesthesia	■ Endoscopic release is very difficult with local anesthesia, as the liquid anesthetic obscures visualization.

POSTOPERATIVE CARE

- We do not use postoperative splinting, but rather a soft dressing that the patient removes after 24 to 48 hours. We encourage use of the hand right away to encourage nerve gliding and prevent adhesion formation.
- We do not routinely refer our patients to hand therapy postoperatively. Therapy can be useful in specific cases such as desensitization for abnormal postoperative hypersensitivity or if there is stiffness or immobility.

OUTCOMES

- A Cochrane systematic review found that both surgical and nonoperative treatments of CTS are effective, but surgery produces a longer-lasting relief of

symptoms than nonoperative therapies.

- Surgical release yields continued improvement for around 12 months postoperatively, whereas improvements from nonoperative therapies plateau at around 3 months.¹

COMPLICATIONS

- Postoperative recurrence has been reported in 3% to 20% of cases.^{16,17}
- Etiologies of persistence or recurrence include incompletely released TCL, abundant scar formation from a number of causes, neuropathy of other etiology (eg, polyneuropathy), and psychosocial factors.¹⁶
- Serious complications are rare but include injury to the median nerve, recurrent motor branch, or palmar cutaneous branch.
- Other complications include painful or hypertrophic scar, hematoma, infection, and wound healing problems.

CHAPTER Ulnar Tunnel Syndrome

Mary Claire Manske and Jason H. Ko

DEFINITION

- Ulnar tunnel syndrome, first described by DuPont et al. in 1965, is a compressive neuropathy of the ulnar nerve at the wrist that presents with a variable constellation of sensory and motor symptoms, depending on the site of nerve compression within the ulnar tunnel.¹
- The ulnar tunnel is commonly referred to as Guyon canal after Jean Casimir Felix Guyon, a French surgeon who first described this anatomic space in 1861.²

ANATOMY

- The ulnar tunnel is a fibro-osseous canal that extends from the proximal edge of the volar carpal ligament to the hook of the hamate and the fibrous arch of the hypothenar muscles distally.
- Medially, it is bordered by the pisiform, flexor carpi ulnaris (FCU), and abductor digit minimi; laterally, it is limited by the hook of the hamate, transverse carpal ligament, and extrinsic flexor tendons.
- The roof of the ulnar tunnel is composed of the volar carpal ligament, palmaris brevis, and hypothenar fascia; the floor is formed by the transverse carpal ligament, pisohamate ligament, pisometacarpal ligament, and opponens digiti minimi³ (**FIG 1A**).
- The contents of the ulnar tunnel include the ulnar nerve, ulnar artery and venae comitantes, and fat. The ulnar nerve is ulnar and dorsal to the ulnar artery.
- In the distal forearm, the ulnar nerve travels volar to the flexor retinaculum before entering the ulnar tunnel. Although variations exist,⁴ the ulnar nerve bifurcates within the tunnel into superficial and deep branches approximately 6

mm distal to the distal pole of the pisiform.

- The superficial branch innervates the palmaris brevis and then continues as a sensory nerve, providing sensation to the hypothenar eminence, small finger, and ulnar side of the ring finger.

FIG 1 • A. Anatomy of the ulnar tunnel. The ulnar tunnel is defined dorsally by the transverse carpal ligament; volarly by the volar carpal ligament; ulnarly by the pisiform, FCU, and ADM; and radially by the hook of the hamate. **B.** Anatomy of the ulnar nerve in the ulnar tunnel. The dorsoulnar fibers of the ulnar nerve become the deep motor branch innervating the intrinsic hand muscles, while the volar-radial fibers provide sensory fascicles to the small finger and ulnar side of the ring finger.

- After passing through the ulnar tunnel, the deep motor branch of the ulnar nerve runs through the pisohamate hiatus just distal to the ulnar tunnel, which is bordered by the pisohamate ligament dorsally and by the fibrous arch of the hypothenar fascia volarly. The deep motor branch curves around the hook of the hamate to innervate the abductor digiti minimi (ADM), flexor digiti minimi, opponens digiti minimi, interossei, third and fourth lumbricals, adductor pollicis, and flexor pollicis brevis (**FIG 1B**).

- The ulnar nerve at the wrist has been divided into three zones, which can be used to correlate clinical symptoms to the site of compression.^{2,5,6}
- Zone I: From the proximal edge of the volar carpal ligament to the bifurcation of the ulnar nerve into motor and sensory branches. Compression in zone I results in intrinsic muscle weakness and sensory deficits over the hypothenar eminence and small and ring fingers.
- Zone II: From just distal to the bifurcation to the fibrous arch of the hypothenar muscles and contains the deep motor branch of the ulnar nerve. Compression in this zone presents with ulnar-innervated intrinsic motor weakness and intact sensation in the ulnar nerve sensory distribution.
- Zone III: Also begins just distal to the bifurcation and includes the sensory branch of the ulnar nerve. Compression at this level results in diminished sensation in the volar aspect of the small finger and volar ulnar ring finger.

PATHOGENESIS

- Many cases of ulnar tunnel syndrome are idiopathic.⁷ Space-occupying lesions, aberrant musculature, carpal tunnel syndrome, and acute and chronic trauma have also been implicated in the pathogenesis of ulnar nerve compression at the wrist.
- Space-occupying masses in the ulnar tunnel are reported to cause compression of the ulnar nerve or its branches, including ganglia, lipomas, ulnar artery thrombosis, ulnar artery pseudoaneurysm, hemangioma, osteoarthritis and rheumatoid arthritis, edema, proliferative synovitis, and bony deformity.
- Hypertrophic hypothenar muscles or anomalous muscles (hypothenar adductor) may cause ulnar nerve compression.
- Carpal tunnel syndrome may cause compression of the ulnar nerve distally, as increased pressure in the carpal tunnel is transmitted to the adjacent ulnar tunnel.
 - Seventy-one percent of patients with ulnar tunnel syndrome have a concomitant diagnosis of carpal tunnel syndrome.⁷
- Fractures and dislocations
 - Hook of hamate fractures: Fracture displacement or associated hematoma and edema may compress the ulnar nerve.
 - Dorsally displaced distal radius fractures and other carpal fractures can cause ulnar nerve palsies secondary to traction on the ulnar nerve or edema.
- Chronic compression

- “Handlebar palsy” in long-distance cyclists who place prolonged pressure on the hypothenar area
- Chronic repetitive microtrauma or vibration
 - “Hypothenar hammer syndrome” in patients who use high-impact vibratory equipment with the wrist extended (eg, jackhammer) results in direct trauma to the ulnar artery leading to thrombosis, which may compress the ulnar nerve and/or cause ischemia.

PATIENT HISTORY AND PHYSICAL FINDINGS

- History and physical examination findings may be purely sensory, purely motor, or mixed sensory and motor, depending on the location of pathology.
- History
 - Sensory complaints: numbness and/or paresthesias in small and ring finger
 - Patients with ulnar tunnel syndrome do not present with sensory disturbance over the dorsal aspect of the hand, given that the dorsal sensory branch of the ulnar nerve supplying this area branches from the ulnar nerve proximal to the ulnar tunnel.
 - Cold intolerance or pain in the ring and small fingers
 - Motor deficits: clumsiness, loss of coordinated hand function, weakness of pinch and grasp, clawing
 - History of trauma
 - Acute: direct blow or sports injury (consider fractures, dislocation)
 - Chronic: use of power tools, cycling (consider ulnar artery thrombosis, pseudoaneurysm, or compression)
 - Comorbid medical conditions: rheumatoid arthritis, osteoarthritis, diabetes mellitus, carpal tunnel syndrome
- Physical Examination
 - Inspection: intrinsic muscle atrophy/wasting or clawing; mass or fullness; ecchymosis, swelling, or other evidence of trauma; compare to contralateral upper extremity
 - Palpation: tenderness may indicate fracture; identify presence of a mass (ganglia, lipomas)
 - Sensory exam: decreased sensation to light touch in small and ulnar ring finger; Semmes-Weinstein monofilament or two-point discrimination test
 - Motor exam: intrinsic motor weakness, index finger abduction (assessment of the first dorsal interosseous muscle), or the cross-finger test (asking the

patient to cross the middle finger over the index finger to assess the first volar and second dorsal interossei)

■ Special motor tests

- Froment sign: Positive test when patient is unable to use adductor pollicis for lateral pinch. Instead, patients compensate with the median nerve innervated flexor pollicis longus to flex the thumb interphalangeal joint. Positive test indicates dysfunction of ulnar nerve motor fibers, although it does not localize the site of the lesion.
- Jeanne test: Test is positive, indicating ulnar motor neuropathy, when the patient hyperextends the metacarpophalangeal joint to compensate for weak adductor pollicis during lateral pinch.
- Wartenberg sign: Inability to adduct the small finger secondary to paralysis of the third palmar interosseous muscle. Positive test indicates an ulnar motor neuropathy.

■ Vascular exam: palpation of radial and ulnar artery pulses, bruits, or thrills; Doppler examination of radial and ulnar artery; Allen test to assess ulnar artery patency

■ Provocative tests: Tinel and Phalen test over pisiform (Phalen test over pisiform is more sensitive than Tinel for ulnar tunnel syndrome)⁸

■ Must rule out alternative sites of nerve compression: cubital tunnel syndrome, carpal tunnel, cervical radiculopathy, thoracic outlet syndrome

IMAGING

■ Electrodiagnostic studies are indicated in nearly all patients with a suspected diagnosis of ulnar tunnel syndrome. The need for additional imaging is determined by the suspected structural etiology of the patient's ulnar tunnel symptoms; bony pathology requires x-ray and/or CT scan; vascular pathology should be evaluated with ultrasound or contrast arteriography; soft tissue masses should be worked up with an MRI. In addition, elbow or cervical spine imaging (x-rays, MRI) may be indicated if there is concern for more proximal pathology.

■ Electrodiagnostic studies are useful to confirm and localize ulnar nerve entrapment.

- Conduction velocity of the ulnar nerve across the elbow and the wrist can determine the location of ulnar nerve entrapment (elbow, wrist, zone I, II, or III).
- The most sensitive electrodiagnostic study for ulnar tunnel syndrome is the

distal motor latency to the first dorsal interosseous combined with conduction velocity across the wrist (90% sensitivity).⁹

- Zone I lesions are characterized by decreased sensory responses and prolonged latency to the first dorsal interosseous and ADM. Zone II lesions show prolonged latency to the first dorsal interosseous (and possibly hypothenar muscles) with normal sensory findings. Zone III lesions show only decreased ulnar sensory responses without motor deficits.¹⁰

■ Radiographic studies

- Posteroanterior, lateral, and oblique views of the wrist are useful when fracture or dislocation is the suspected etiology of the patient's ulnar nerve symptoms.
- A 30-degree supinated oblique view with the thumb abducted or carpal tunnel view is useful when there is clinical concern for pisotriquetral joint pathology or hook of the hamate fracture, respectively.
- The indication for obtaining a CT scan in the setting of ulnar tunnel symptoms is similar to that for x-rays. CT scan is particularly useful in detecting hook of hamate fractures.
- Magnetic resonance imaging is useful for identifying and localizing soft tissue masses, aberrant musculature, vascular anomalies, and hook of hamate fractures.
- Ultrasound has similar indications to MRI but is less costly.¹¹
- Arteriography serves as the standard for evaluating ulnar artery pathology (eg, thrombosis, pseudoaneurysm).¹²

DIFFERENTIAL DIAGNOSIS

- Cubital tunnel syndrome or proximal compression of the ulnar nerve
- Carpal tunnel syndrome
- Cervical radiculopathy
- Neuromuscular disorders (Charcot-Marie-Tooth, amyotrophic lateral sclerosis)
- Malignant peripheral nerve sheath tumors
- C8-T1 brachial plexopathy
- Central nerve system lesion
- Poliomyelitis

NONOPERATIVE MANAGEMENT

- Nonoperative management consisting of activity modification, rest, and a short

course of bracing in a neutral wrist splint may be considered in patients without motor symptoms.

- Activity modification for ulnar tunnel symptoms secondary to hypothenar eminence compression. Cyclists with handlebar palsy may modify the position of their handlebars to prevent the compression of the ulnar base of the palm.
- Patients with hypothenar hammer syndrome without thrombosis and symptoms of digital ischemia may attempt nonoperative intervention, consisting of the following:
 - Smoking cessation, avoidance of trauma, protective gloves, change of occupation, cold avoidance, and calcium channel blockers¹³
- Cortisone injections are not indicated for ulnar tunnel syndrome because inflammation is rarely the cause of ulnar tunnel syndrome and there is a high risk of neurovascular injury when injecting into this confined space.

SURGICAL MANAGEMENT

- Indications:
 - Failure of nonoperative intervention
 - Loss of two-point discrimination
 - Presence of intrinsic muscle weakness or atrophy
 - Severe electrodiagnostic abnormalities
- Operative intervention for ulnar tunnel syndrome consists of ulnar nerve decompression through the distal ulnar tunnel. Additional procedures may be performed as needed to address the causative pathology.
 - Space-occupying mass requires mass excision in addition to ulnar nerve decompression in the ulnar tunnel.
 - Ulnar artery thrombosis or aneurysm should be treated with artery reconstruction and ulnar nerve decompression.
 - Ulnar tunnel syndrome secondary to carpal tunnel syndrome often improves with carpal tunnel release alone, and additional release of the ulnar tunnel is not recommended.
- Optimal outcomes are achieved when all sources of pathology are addressed.

Preoperative Planning

- Indications for operative intervention include failure of nonoperative intervention, motor weakness or loss of two-point sensibility in the ulnar nerve distribution due to ulnar nerve compression distally, or severe electrodiagnostic

changes involving the ulnar nerve at the wrist.

- Electrodiagnostic studies should be reviewed to confirm the precise location of ulnar nerve compression and appropriate site of decompression.
- Relevant imaging studies must be reviewed to allow the surgeon to address all etiologies of ulnar nerve symptoms.

Positioning

- Patients are positioned supine on a well-padded operating table with the affected limb on a hand table.
- The operating table is turned so that the hand table faces the center of the room.
- A nonsterile tourniquet is applied to the affected upper extremity.

Approach

- A volar approach to the ulnar nerve at the wrist is the most direct approach and allows accesses to the relevant pathology.

TECHNIQUES

■ Ulnar Tunnel Release and Ulnar Nerve Decompression

Exposure

- Operative limb is elevated and exsanguinated with an elastic bandage immediately prior to tourniquet elevation.
- Alternatively, or in addition to a tourniquet, 0.25% bupivacaine with epinephrine can be injected into the planned incision site for postoperative comfort and intraoperative hemostasis.
- Identify landmark for incisions: The pisiform is easily palpated in the ulnar base of the palm. The hook of the hamate is located 1 cm distal and 1 cm radial to the pisiform and can be palpated.
- A no. 15 blade scalpel is used to make a 4-cm longitudinal or curvilinear incision through the skin paralleling the thenar crease between the pisiform and hook of the hamate, approximately 6 mm ulnar to the thenar crease (**TECH FIG 1**).

- To extend proximally into the forearm, the incision should cross the wrist crease obliquely and may continue proximally adjacent to the flexor carpi ulnaris tendon.
- To extend the incision distally into the palm, the incision may be extended in a zigzag or Bruner fashion.

Dissection

- Tenotomy scissors are used to dissect through the subcutaneous tissue, and gentle skin retraction is provided by two double-prong skin hooks.

TECH FIG 1 • Incision for ulnar tunnel release. In the palm, a longitudinal incision is centered between the pisiform and hook of the hamate. The incision crosses the wrist flexion crease obliquely before extending proximally adjacent to the flexor carpi ulnaris (FCU)

tendon. *P*, pisiform; *H*, Hook of hamate.

TECH FIG 2 • In the forearm, the ulnar neurovascular bundle is identified deep to the antebrachial fascia between the FCU tendon and tendons of the finger flexors. At this location, the ulnar nerve is deep and ulnar to the artery.

- A cutaneous branch of the ulnar nerve crosses the distal aspect of the incision in 15% of patients. Care must be taken to identify and protect this nerve to avoid a painful neuroma if injured.
- Dissection continues until the volar carpal tunnel and palmaris brevis are identified.
- Proximally in the forearm, the ulnar neurovascular bundle is identified deep to the antebrachial fascia between the flexor carpi ulnaris and the finger flexor tendons. The ulnar nerve is located ulnar and deep to the ulnar artery (**TECH FIG 2**).

Ulnar Nerve Decompression

- The ulnar nerve is carefully dissected from proximal to distal, through the ulnar tunnel.
- The volar carpal ligament and palmaris brevis (roof of the ulnar tunnel) are incised, staying ulnar to the hook of the hamate, so as not to inadvertently

enter the carpal tunnel.

- Within the ulnar tunnel, the ulnar nerve is gently retracted medially to identify and decompress the deep motor branch.
- To identify the deep motor branch, locate the oblique fibers of the proximal edge of the hypothenar fascia. Immediately proximal to this leading edge, 1 to 2 mm of the deep motor branch is visible as it dives deep to the hypothenar fascia to enter the pisohamate hiatus and curves around the hook of the hamate.
- A small blunt elevator may be placed deep to the proximal edge of hypothenar fascia to protect the deep motor branch, and this fascia is then released (**TECH FIG 3A**).
- The deep motor branch is then followed around the hook of the hamate, and all tendinous bands of the hypothenar musculature must also be divided (**TECH FIG 3B**).
- If the deep motor branch is compressed more distally in the palm, it may be followed along the interosseous fascia (deep to the flexor tendons and superficial palmar arch) to its terminus in the adductor pollicis.

TECH FIG 3 • A. A Freer elevator has been placed beneath the leading edge of the hypothenar fascia. **B.** The sensory branch and deep motor branch of the ulnar nerve have been decompressed.

- Within the canal, care must be taken to protect the small vessels running with the motor branch.
- After releasing the ulnar nerve and the deep motor branch, the floor of the ulnar tunnel is evaluated for masses or anomalous muscles, which are then

excised. In the case of a ganglion cyst, the stalk of the cyst is identified and ablated at its origin.

- After the ulnar nerve and its distal branches have been decompressed, the wound is thoroughly irrigated with sterile saline and the tourniquet deflated. Meticulous hemostasis is achieved with bipolar electrocautery.

Wound Closure and Dressing

- The incision is closed with 4-0 nylon suture in a horizontal or simple interrupted fashion.
- If local anesthetic, such as 0.25% bupivacaine, has not previously been injection, it may be injected into the incision site at this time for postoperative comfort.
- A nonadherent dressing is applied directly to the wound, and a sterile, bulky soft dressing is placed.
- Typically, a splint is not needed, unless a ganglion cyst was excised or the dissection was extensive.

PEARLS AND PITFALLS

Diagnosis	Evaluate for extrinsic sources of compression based on suspected pathology. ■ Osseous pathology: radiographs, CT ■ Vascular pathology: Ultrasound, contrast arteriogram ■ Soft tissue mass: MRI
Incision	■ Fifteen percent of patients have a cutaneous branch of the ulnar nerve in the distal aspect of this incision. Avoid injury to the nerve here to prevent a painful neuroma.
Entering the ulnar tunnel	■ Stay ulnar to the hook of the hamate to avoid entering the carpal tunnel.
Identification of the deep motor branch	■ Identify the oblique fibers of the hypothenar fascia at the proximal edge of the hypothenar muscles and carefully release these fibers to expose and decompress the ulnar motor branch.
Release of	■ Ensure complete nerve decompression, including complete release

**the deep
motor branch**

of the tendinous bands of the hypothenar muscles.

Hemostasis

- Preserve the small vessels running with the deep motor branch to avoid having to cauterize vessels adjacent to the nerve.
-

POSTOPERATIVE CARE

- Apply a soft bulky dressing to the wrist postoperatively, and active range of motion can be initiated immediately to minimize scarring around the nerve.
- The bulky surgical dressing is removed on postoperative day 1 or 2 and replaced with a clean gauze dressing or bandage, if necessary.
- Night splinting with the wrist in a neutral position may be used for 2 weeks for patient comfort.
- Strengthening exercises may be initiated at 4 to 6 weeks. Patients may gradually increase activities as tolerated at this time.

OUTCOMES

- There are limited data on the outcome of ulnar tunnel release and decompression.
- Murata et al. retrospectively reported their outcomes in 31 patients with ulnar tunnel syndrome with a variety of causes treated with ulnar tunnel decompression.⁷
 - The authors reported improvement in subjective symptoms and two-point discrimination in all patients (from a preoperative mean of 7.0 and 6.9 mm in the ring and small fingers, respectively, to 5.4 and 5.3 mm postoperatively), although no statistical analysis was provided.
 - Five patients had persistent symptoms in the ring and/or small fingers.

COMPLICATIONS

- There are few studies reporting the type and incidence of complications of ulnar tunnel release.
- Potential complications include the following:
 - Incomplete relief of symptoms (persistent numbness, weakness)
 - Iatrogenic injury to the ulnar nerve or artery branches, especially to the deep motor branch as it enters the pisohamate hiatus
 - Hematoma resulting from injury to vascular plexus around the ulnar nerve branches and failure to achieve hemostasis prior to wound closure

- Wound infection
- Wound dehiscence
- Meticulous hemostasis, careful dissection, and knowledge of the ulnar nerve and artery branching anatomy and its variations are helpful in avoiding complications.

CHAPTER Cubital Tunnel Syndrome

Mary Claire Manske and Jason H. Ko

DEFINITION

- Cubital tunnel syndrome is symptomatic ulnar nerve dysfunction resulting from a combination of compression, traction, friction, and nerve instability at or near the elbow.
- The cubital tunnel is a fibro-osseous canal through which the ulnar nerve passes at the level of the medial elbow and is thought to be the most common site of nerve pathology.

ANATOMY

- The ulnar nerve is composed of fibers from the C8 and T1 nerve roots, although additional contributions from the C5, C6, C7, or T2 roots are common.
 - It arises from the medial cord of the brachial plexus and enters the arm by passing deep to the pectoralis major muscle, medial to the brachial artery.
- At 8 to 10 cm proximal to the medial epicondyle, the nerve pierces the medial intermuscular septum from anterior to posterior and descends through the arm along the posterior aspect of the medial intermuscular septum.
 - At this location, there is often a thick fascial band (the internal brachial ligament) spanning from the medial intermuscular septum to the medial head of the triceps, commonly referred to as the arcade of Struthers (**FIG 1**).
- The ulnar nerve travels posterior to the elbow via the cubital tunnel to enter the anterior forearm. The cubital tunnel is a fibro-osseous space bordered by the medial epicondyle anteriorly, the olecranon posteriorly, the oblique and posterior bands of the ulnar collateral ligament medially (the “floor” of the tunnel), and Osborne (or arcuate) ligament laterally (the “roof” of the tunnel).

Within the cubital tunnel, the ulnar nerve commonly provides articular branches to the elbow and motor branches to the flexor carpi ulnaris (FCU) (between 1 and 4 branches, arising from 4 cm proximal to the elbow to 10 cm distal to the medial epicondyle). The ulnar nerve provides motor branches to the ulnar two flexor digitorum profundus, which arise approximately 3 cm distal to the medial epicondyle.

- After passing through the cubital tunnel, the ulnar nerve travels deep to the fibrous aponeurosis of the FCU to pass between the two heads of the FCU and into the forearm along the undersurface of the FCU into the distal forearm.

FIG 1 Anatomy of the cubital tunnel.

PATHOGENESIS

- Four pathogenic mechanisms have been implicated in cubital tunnel syndrome: compression, traction, friction, and instability.
- Compression: The ulnar nerve may be compressed anywhere along its course, but the most common clinical sites of compression are the arcade of Struthers, the median intermuscular septum, medial epicondyle, anconeus epitrochlearis (if present), the cubital tunnel, and the deep flexor-pronator aponeurosis

- The cubital tunnel is round and spacious with elbow extension but narrows and becomes elliptical with the elbow flexed, decreasing the volume of the tunnel by 55%.^{1,2}
- Decreased cubital tunnel volume results in a four- to fivefold increase in extra- and intraneural pressure of the ulnar nerve.³
- Both blood flow and axonal transport are impaired with external nerve compression; as pressure increases, the nerve tissue thickens and nerve conduction is impaired.^{1,4-6}
- Less common sources of ulnar nerve compression include soft tissue masses (eg, ganglia, tumors), hypertrophic synovium, cubitus valgus, and osteophytes.
- Traction⁷: The course of the ulnar nerve around the medial epicondyle places tension on the ulnar nerve where it crosses the elbow and enters the forearm.
 - The ulnar nerve elongates by 4 to 8 mm when the elbow is flexed. This stretch is further increased with the shoulder abducted and the wrist extended.
 - Stretch of the ulnar nerve results in both reduced blood flow and impaired conduction.
- Friction: Although the nerve naturally experiences some traction and excursion with elbow motion, repetitive elbow motion or subluxation of the nerve can cause traction neuritis, inflammation, and endoneurial edema, decreasing the nerve's ability to glide smoothly.¹
- Instability: Subluxation of the ulnar nerve out of the cubital tunnel or over the medial epicondyle may result in elbow pain, a snapping sensation, numbness, or intrinsic motor weakness.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Sensory
 - Numbness and paresthesia in the ring and small finger
 - Dorsoulnar hand numbness helps differentiate cubital tunnel syndrome/proximal ulnar nerve compression from ulnar tunnel syndrome at the wrist.
 - Presence of numbness or paresthesia in the medial forearm distinguishes C8 radiculopathy from cubital tunnel syndrome.
 - Depending on severity and chronicity, numbness may be intermittent or constant.

- Motor
 - Hand clumsiness, loss of dexterity
 - Weakness of pinch and grip
 - Inability to adduct or abduct the fingers
 - Intrinsic muscle atrophy, clawing of the ulnar two digits, with severe ulnar nerve compression
 - Pain in the medial elbow or forearm
- Physical exam
 - Inspection: Intrinsic muscle atrophy/wasting or clawing; compare to contralateral upper extremity
 - Palpation: Medial elbow tenderness; subluxation or perching of ulnar nerve over medial epicondyle with elbow flexion and extension
 - Sensory exam: Decreased sensation to light touch in small and ulnar ring finger; decreased sensation over dorsoulnar hand. Semmes-Weinstein monofilament or 2-point discrimination test
 - Motor exam: Intrinsic motor weakness indicates compromise of ulnar motor nerve fibers. Assess by testing index finger abduction (first dorsal interosseous muscle) or performing the cross-finger test (asking the patient to cross the middle finger over the index finger to assess the first volar and second dorsal interossei).
 - Additional motor tests:
 - Froment sign: Positive test when patient is unable to use adductor pollicis for lateral pinch. Instead, patients compensate with the flexor pollicis longus, which is innervated by the median nerve, to flex the thumb interphalangeal joint. Positive test indicates dysfunction of ulnar nerve motor fibers, although it does not localize the site of the lesion.
 - Jeanne test: Test is positive, indicating ulnar motor neuropathy, when the patient hyperextends the metacarpophalangeal joint to compensate for weak adductor pollicis during lateral pinch.
 - Wartenberg sign: Inability to adduct the small finger secondary to paralysis of the third palmar interosseous muscle. Positive test indicates an ulnar motor neuropathy.
 - Provocative tests:
 - Tinel sign at elbow: Percussion over ulnar nerve at medial epicondyle reproduces paresthesias in ring and small finger in patients with cubital tunnel syndrome.

- Elbow flexion test: Elbow flexion, forearm supination, and wrist extension for 3 minutes elicit paresthesia in ulnar nerve distribution in patients with cubital tunnel syndrome.
- Pressure provocation test: Manual pressure over ulnar nerve in cubital tunnel elicits ulnar nerve paresthesia.
- Scratch collapse test⁸: Examiner scratches the skin over the compromised ulnar nerve while the patient performs sustained resisted shoulder external rotation with the arms adducted and the elbow flexed. A positive test is indicated by brief loss of ability to maintain resisted external resistance (ie, collapse).
- Must rule out alternative sites of nerve compression:
 - Guyon canal (tenderness over hook or hamate or pisiform)
 - Cervical radiculopathy (neck pain, Spurling test, more proximal motor and sensory involvement)
 - Carpal tunnel syndrome (thenar atrophy or weakness; sensory disturbance in radial-sided digits; Tinel, Phalen, Durkan test positive over carpal tunnel)
 - Lower brachial plexus lesion
 - Thoracic outlet syndrome (Roos test, Adson maneuver)

IMAGING

- Electrodiagnostic testing is useful to confirm a diagnosis of ulnar nerve dysfunction, localize the site of compression, and quantify the severity.
- The following criteria are used to diagnose cubital tunnel syndrome electodiagnostically⁹:
 - Absolute conduction velocity less than 50 m/s
 - Decreased conduction velocity of greater than 10 m/s across the elbow
 - Decreased amplitude of at least 20%
 - Absent sensory response
 - Evidence of motor atrophy
- X-rays should be obtained selectively when there is clinical concern for an osseous abnormality causing ulnar nerve compression.
- Elbow radiographs are useful in suspected cases of elbow osteoarthritis, rheumatoid arthritis, trauma, or cubitus valgus deformity
- Chest radiographs may identify a cervical rib causing thoracic outlet syndrome or a Pancoast tumor (suspected in patients with ulnar nerve

symptoms, shoulder pain, and history of smoking)

- On ultrasound, patients with cubital tunnel syndrome have an increased cross-sectional area of the ulnar nerve compared to patients without cubital tunnel syndrome.
- Ulnar nerve cross-sectional area of 0.10 cm^2 or higher on ultrasound of the ulnar nerve within 4 cm of the medial epicondyle is 93% sensitive and 98% specific for cubital tunnel syndrome.¹⁰
- Morphologic and signal changes in the ulnar nerve have been observed on MRI in cubital tunnel syndrome.
- MRI has been reported to be both sensitive and specific in diagnosing cubital tunnel syndrome but is not routinely used.^{11,12}

DIFFERENTIAL DIAGNOSIS

- Cervical radiculopathy
- Ulnar tunnel syndrome
- Lower brachial plexopathy
- Motor neuron disease (eg, amyotrophic lateral sclerosis, Charcot-Marie-Tooth)
- Guillain-Barré syndrome
- Diabetic neuropathy

NONOPERATIVE MANAGEMENT

- Initial treatment of cubital tunnel syndrome in patients without constant numbness or motor atrophy is nonoperative.
- Nonoperative treatment consists of patient education, activity modification (discontinue triceps exercises, pad medial elbow when resting on a hard surface), postural modification (avoidance of prolonged elbow flexion or resting medial elbow on a hard surface), night splinting (to prevent the elbow from flexing beyond 40 to 50 degrees during sleep), and/or nerve gliding exercises.¹³
- The recommended duration of nonoperative treatment is 3 months in patients with mild or moderate symptoms and 6 weeks in patients with severe symptoms.
- A comprehensive course of nonoperative intervention has been shown to resolve symptoms in 42% of patients with mild cubital tunnel syndrome, 34% of patients with moderate symptoms, and 20% of patients with severe symptoms.¹⁴

- Steroid injection is not recommended, as this has not been shown to provide any benefit in the treatment of cubital tunnel syndrome and presents a risk of nerve injury.¹⁵

SURGICAL MANAGEMENT

Preoperative Planning

- Indications for operative intervention include failure of nonoperative intervention, muscle atrophy or weakness, loss of two-point sensibility in the ulnar nerve distribution, or severe electrodiagnostic changes involving the ulnar nerve in the proximity of the elbow.¹⁶
- Assess stability of ulnar nerve preoperatively, as this guides surgical intervention; patients with ulnar nerve instability are not candidates for in situ decompression.

Positioning

- Patients are positioned supine on a well-padded operating table or stretcher.
- The operative extremity is positioned on a hand table. The patient's shoulder should be placed as close to the hand table as possible.
- We recommend against the use of a nonsterile tourniquet, as this may encroach upon the surgical field when anterior transposition is required.

Approach

- A direct approach to the ulnar nerve on the medial side of the elbow is utilized.

TECHNIQUES

■ In Situ Cubital Tunnel Decompression

- After the operative limb is prepped and draped, a surgical marking pen is used to mark the medial epicondyle, olecranon, and medial intermuscular septum. If a tourniquet is used, a sterile tourniquet should be applied to the upper extremity as proximally as possible. An alternative to the tourniquet is to inject the planned incision subcutaneously with local anesthetic containing epinephrine.
- If a tourniquet is used, the extremity is exsanguinated with an elastic

bandage and the tourniquet elevated to 250 mm Hg.

- A 3- to 5-cm incision along the course of the ulnar nerve midway between the medial epicondyle and olecranon is made with a scalpel just through the dermis (**TECH FIG 1A**).
- The subcutaneous tissues are dissected with tenotomy scissors in line with the skin incision down to the level of the deep brachial fascia proximally and the antebrachial fascia distally.
- Care must be taken to identify and protect branches of the medial antebrachial cutaneous (MABC) nerve, which lie within the subcutaneous fat just over the muscle fascia from 6 cm proximal to 6 cm distal to the medial epicondyle.¹⁷
- The ulnar nerve is identified proximally, deep to the deep brachial fascia and posterior to the medial intermuscular septum.
- The fascia overlying the ulnar nerve proximally is released, beginning 8 cm proximal to the medial epicondyle (**TECH FIG 1B**).
- The nerve is followed distally, releasing the overlying fascia bands to decompress the nerve. Specific structures released include the arcade of Struthers, deep brachial fascia, Osborne ligament, and deep flexor-pronator aponeurosis. Care is taken not to dissect around the ulnar nerve circumferentially.
- The deep flexor-pronator aponeurosis should be released for a minimum of 4 cm distal to where the ulnar nerve enters the forearm between the two heads to the flexor carpi ulnaris (FCU).
- With blunt digital dissection, a finger should be passed along the course of the ulnar nerve as it passes deep to the flexor-pronator mass to ensure that all constricting bands of the deep flexor-pronator aponeurosis have been released (**TECH FIG 1C**).
- Following decompression, the ulnar nerve is not displaced from its bed, nor is a neurolysis performed.
- The elbow is taken through its full arc of motion, and the stability of the ulnar nerve is assessed.
 - If the nerve subluxates or perches on the medial epicondyle, an anterior transposition should be performed.
 - In addition, evaluation for any residual points of ulnar nerve compression should be performed. In particular, the medial intermuscular septum should be examined to ensure the nerve does not kink on the septum with elbow

range of motion; if it does, that section of the medial intermuscular septum should be excised, with care to cauterize or ligate the branches of the profunda brachii artery that cross the septum.

- If a tourniquet has been used, it is released and meticulous hemostasis obtained with bipolar electrocautery.
- The skin may be injected with local anesthetic if this was not performed previously.
- The dermis is closed with a 3-0 absorbable suture in a buried interrupted fashion. The skin is closed with an absorbable monofilament suture.
- A bulky soft dressing is applied and elbow range of motion is initiated within the first few days postoperatively. Patients are permitted to perform light activities of daily living (eg, dressing, self-care, feeding) but no heavy lifting or sports for 2 weeks.

TECH FIG 1 • **A.** A 3- to 5-cm incision is made along the course of the ulnar nerve centered between the medial epicondyle and the olecranon. **B.** The fascia overlying the ulnar nerve proximally is released,

beginning 8 cm proximal to the medial epicondyle (*red arrow*) and proceeding distally. **C.** The deep aponeurosis of the flexor-pronator mass is released over the ulnar nerve, as it dives between the two heads of the FCU (*red arrow*). (Proximal is to the left and distal to the right in all parts.)

■ **Transposition of the Ulnar Nerve**

- Typically, in situ decompression of the ulnar nerve is the first-line treatment for cubital tunnel syndrome.
- However, if there is subluxation of the ulnar nerve, subcutaneous or submuscular transposition of the ulnar nerve may be indicated at the time of decompression.
- For the treatment of recurrent cubital tunnel syndrome, subcutaneous or submuscular transposition of the ulnar nerve is the treatment of choice.
 - Submuscular transpositions are usually reserved for patients who have failed previous subcutaneous transposition.
- The operative extremity is prepped and draped in the usual sterile fashion.
- A sterile tourniquet may be applied to the operative extremity as proximally as possible. An alternative to the tourniquet is to inject the planned incision with local anesthetic containing epinephrine.
- A surgical marking pen is used to mark the anatomic landmarks: medial epicondyle, olecranon, and medial intermuscular septum.
- If a tourniquet is used, the limb is exsanguinated with an elastic bandage and the tourniquet is elevated to 250 mm Hg.
- A 10-cm incision is made over the course of the ulnar nerve centered between the medial epicondyle and olecranon. Proximal to the medial epicondyle, the incision is made along the palpable course of the medial intermuscular septum. Distally, the incision follows the course of the ulnar nerve as it travels between the two heads of the FCU.
- An ulnar nerve decompression is performed as described above for in situ ulnar nerve decompression.
- A half-inch latex-free Penrose drain is placed around the nerve to allow it to be manipulated atraumatically. The ends of the Penrose drain are sutured

together with 4-0 nylon suture.

- We recommend against using a vessel loop around the nerve or placing a hemostat clamp on the Penrose drain, as both of these may cause unnecessary trauma to the nerve and increase the likelihood of a neurapraxic injury.
- Using tenotomy scissors, the ulnar nerve is circumferentially dissected to free it from surrounding tissues and the bed in which it rests.
- The longitudinally running superior ulnar collateral vessels that accompany the nerve should remain with the nerve as distally as possible, but it is necessary to ligate the vessels as they penetrate the FCU muscle belly.
- To avoid compression of the nerve by the medial intermuscular septum after it is transposed, the distal segment of the medial intermuscular septum should be excised from its insertion on the humerus. Branches of the profunda brachii artery cross the septum, and these need to be ligated or cauterized.

Submuscular Transposition of the Ulnar Nerve

- The subcutaneous tissues are elevated off the flexor-pronator fascia.
- A step-cut is made in the flexor-pronator fascia, such that the anterior musculofascial flap is distally based and the posterior fascial flap is proximally based on the medial epicondyle.
 - The flaps should be approximately 3 cm in length to avoid compression on the ulnar nerve when the flaps are coapted (**TECH FIG 2A**).
- The posterior fascial flap is carefully and sharply elevated from the underlying muscle with a scalpel or tenotomy scissors, with care not to disrupt the base of the fascial flap.
- The anterior musculofascial flap is elevated full-thickness, including the superficial head of pronator teres and the common flexor tendon, using monopolar cautery.
 - This allows the anterior musculofascial unit to slide distally, creating a trough for the ulnar nerve, once transposed.
- Within the muscle of the flexor-pronator mass, there are stout fascial septa that need to be excised to prevent them from compressing the ulnar nerve when it is transposed.
 - Care must be taken to identify FCU motor branches of the ulnar nerve that may cross these septa.
- Monopolar electrocautery is used to dissect through the flexor-pronator

muscle in line with the elevated posterior flap to provide a deep muscular bed in which the ulnar nerve may rest.

- Using the Penrose drain, the nerve is gently transposed anteriorly and laid in the previously created muscle trough (**TECH FIG 2B**).
- If the nerve is tethered by motor branches to the FCU, these branches may be separated from the main nerve for up to 6 to 8 cm to allow greater excursion of the ulnar nerve as it is transposed.
- The entire course of the ulnar nerve is examined to ensure there are no points of nerve compression or crimping after it has been transposed.
 - In particular, ensure that all soft tissues proximally have been released, that the nerve is not kinked as it crosses the medial intermuscular septum, and that it is not bending over the superficial or deep flexor-pronator fascia distally.
- Stout, nonabsorbable braided suture is used to coapt the ends of the flaps that were raised from the flexor-pronator fascia, effectively lengthening the musculofascial unit.
 - Figure-of-eight or horizontal mattress suture can be used (**TECH FIG 2C**).
- The elbow is taken through a range of motion from full extension to full flexion.
 - The nerve is inspected to ensure it does not fall out of its bed in the muscle or subluxate posterior to the medial epicondyle.
 - Any dynamic points of compression are also identified and released as necessary.
- If a tourniquet is used, it is now deflated. Meticulous hemostasis is obtained with electrocautery.

TECH FIG 2 • **A.** A step-cut is made in the flexor-pronator fascia to create an anterior distally based myofascial flap and a posterior proximally based fascial flap. *White arrows* indicate medial antebrachial cutaneous nerve. **B.** Full-thickness myofascial flaps are elevated to create a trough in the muscle bed into which the ulnar nerve is transposed. **C.** The ends of the fascial flaps are sutured together to prevent posterior subluxation of the ulnar nerve and effectively lengthening the musculofascial unit. (Distal is to the left and proximal to the right in all parts.)

- The wound is thoroughly irrigated with normal saline.
- The wound is closed with deep dermal buried interrupted sutures using an absorbable suture material. The skin is closed with a running subcuticular absorbable monofilament suture or a nonabsorbable monofilament in a simple or horizontal mattress fashion.
- A sterile soft dressing is applied to the wound, followed by either a soft

compression dressing or a posterior slab long-arm plaster splint, which remains in place for 2 weeks.

- It is important for the patient to be able to perform gentle active range of motion of the elbow in the immediate postoperative period.

Anterior Subcutaneous Transposition of the Ulnar Nerve

- The subcutaneous tissues are elevated off the flexor-pronator fascia.
- An anteriorly based flap of flexor-pronator fascia is sharply elevated from the medial epicondyle and underlying musculature with a scalpel blade or tenotomy scissors.
 - The fascial flap should be approximately 3 cm in length to avoid compression of the ulnar nerve (**TECH FIG 3A,B**).
- Using the Penrose drain, the nerve is gently transposed anteriorly and positioned superficial to the fascial flap (**TECH FIG 3C**).
- If the nerve is tethered by motor branches to the FCU, these branches may be separated from the main nerve for up to 6 to 8 cm to allow greater excursion of the ulnar nerve as it is transposed.
- The entire course of the ulnar nerve is examined to ensure there are no points of nerve compression or crimping after it has been transposed. In particular, ensure that all soft tissues surrounding the nerve proximally have been released, that the nerve is not kinked as it crosses the medial intermuscular septum, and that the nerve is not compressed by the flap in its transposed position.
- The fascial flap is approximated to the deep dermis on the underside of the anterior skin flap, and that point on the superficial surface of the skin can be marked with a marking pen (**TECH FIG 3D; VIDEO 1**).
- Stout, nonabsorbable braided suture is used to suture the free end of the fascial flap to the deep dermis on the underside of the anterior skin flap. Figure-of-eight or horizontal mattress suture may be used.
 - The flap is approximated quite anteriorly so that when the anterior skin flap is then brought down for closure, the fascial flap acts as a “hammock” for the ulnar nerve, keeping it anterior to the medial epicondyle (**TECH FIG 3E**).

TECH FIG 3 • **A.** An anteriorly based flap of flexor-pronator fascia is designed to form a sling for the transposed ulnar nerve. **B.** The fascial flap then elevated from the medial epicondyle and underlying musculature. **C.** The ulnar nerve is transposed anteriorly over the fascial flap. **D.** The fascial flap is sutured to the dermis of the anterior skin flap to function as a “hammock” for the transposed ulnar nerve to prevent posterior subluxation. **E.** The nerve is evaluated throughout the full range of motion of the elbow to ensure that the nerve does not kink, subluxate, or become compressed in its transposed position. (Distal is to the left and proximal to the right in all parts.)

- The elbow is taken through a range of motion from full extension to full flexion.
 - The nerve is inspected to ensure it does not fall out of its bed in the muscle or subluxate posterior to the medial epicondyle.
 - Any dynamic points of compression are also identified and released as necessary (Video 2).
- If a tourniquet is used, it is now deflated. Meticulous hemostasis is obtained with electrocautery.
- The operative field is thoroughly irrigated with normal saline.
- The incision is closed with deep dermal, buried, interrupted sutures using an absorbable suture material.
- The skin is closed with a running subcuticular absorbable monofilament suture or a nonabsorbable monofilament in a simple or horizontal mattress fashion.
 - If an absorbable subcuticular suture is used, Steri-Strips are applied to the incision.
- A sterile bulky soft dressing is applied to the incision, which remains in place for 2 days.
 - After postoperative day 2, it is important that the patient continue to use a

compression dressing to minimize postoperative edema.

- Patients are instructed that they may gently move their elbow and use the extremity for activities of daily living.

PEARLS AND PITFALLS

Superficial dissection

- Care should be taken to preserve branches of the medial antebrachial cutaneous nerve to avoid causing a painful neuroma. These branches cross the medial arm from 6 cm proximal to 6 cm distal to the medial epicondyle.

Deep dissection

- A Penrose drain is loosely looped around the ulnar nerve to manipulate it atraumatically during dissection and transposition.

Hemostasis

- Meticulous hemostasis must be obtained to prevent a hematoma, which could compress the ulnar nerve or lead to wound dehiscence.

Iatrogenic compression

- Secondary points of compression may be introduced after ulnar nerve transposition if care is not taken to release them; in particular, the medial intermuscular septum, the deep septa of the flexor-pronator musculature (with submuscular transposition), and the fascial flaps holding the nerve transposed should be inspected to ensure no compression is present.

Nerve stability

- Inspect the position of the ulnar nerve throughout the full range of motion of the elbow to ensure the nerve does not rest on or subluxate posterior to the medial epicondyle.

POSTOPERATIVE CARE

- In situ decompression or subcutaneous ulnar nerve transposition
 - Patients are placed in a bulky soft dressing, which may be removed on postoperative day 2. They may begin showering at that point, but it is important to continue the use of a compression wrap to minimize postoperative edema.
 - Patients may move the operative extremity and perform activities of daily living postoperatively. Heavier activities (ie, more than “coffee cup” weight bearing) are prohibited. Patients may move the elbow and forearm as pain permits. Patients are encouraged to move their wrist, hand, and digits to

prevent postoperative edema and stiffness.

- Submuscular transposition
 - The use of a bulky soft dressing vs a long-arm splint is at the discretion of the surgeon.
 - It is important for gentle range of motion of the elbow to begin immediately in the postoperative period to minimize scarring along the ulnar nerve.
 - If a long-arm splint is used, it remains in place for 2 week postoperatively. Patients are encouraged to move and use their digits while the splint is in place.
 - If a soft dressing is used, it should remain in place for 2 weeks.
- When the incision is well healed (usually around 2 weeks postoperatively), sutures may be removed if nonabsorbable suture were used. Patients whose incisions are closed with subcuticular absorbable sutures and Steri-Strips are instructed that the Steri-Strips will fall off on their own.
- All patients may allow the incision to get wet in the shower but are restricted from immersing the incision in baths and pools for another week.
- Patients may engage in unrestricted activities as tolerated at 2 weeks postoperatively as long as the incision is well healed.

OUTCOMES

- In situ decompression, subcutaneous transposition and submuscular transposition have all been shown to be effective in the treatment of cubital tunnel syndrome.
 - Most patients experience objective and subjective improvement in sensation, strength, and pain, although persistent subjective sensory abnormalities are common, regardless of surgical technique.
 - Patients express high satisfaction with the outcome of surgical intervention with all procedures.
 - Multiple meta-analyses have demonstrated no difference in outcome in terms of clinical outcomes or conduction velocities.

COMPLICATIONS

- New elbow pain
- Scar tenderness
- Medial elbow and forearm numbness
- Hematoma
- Infection

- Persistent or recurrent symptoms
- The rate of revision surgery following in situ decompression is reported between 3% and 19%.^{18,19}

29 Radial Tunnel Decompression

CHAPTER

Joseph Pirolo and Jason H. Ko

DEFINITION

- Radial tunnel syndrome (RTS) is a pain syndrome caused by compression of the radial nerve and its branches in the proximal forearm.
- Generally characterized by lack of muscle weakness and electrodiagnostic findings

ANATOMY

- The radial tunnel is the space through which the radial nerve and its branches pass in the proximal forearm.
- The tunnel extends approximately 5 cm from the radiocapitellar joint to the proximal edge of the supinator muscle.¹⁻³
- Tunnel boundaries¹⁻³
 - Radial: brachioradialis (BR), extensor carpi radialis longus (ECRL), and extensor carpi radialis brevis (ECRB)
 - Ulnar: brachialis, biceps tendon
 - Floor: radiocapitellar joint capsule, supinator
- Radial nerve branches and sites of compression
 - The radial nerve branches proximal to the superior border of the supinator and forms the radial sensory nerve (RSN) and the posterior interosseous nerve (PIN).
 - The PIN has multiple potential entrapment sites^{2,4-6}
 - Arcade of Frohse (proximal tendinous edge of supinator)
 - Proximal edge of ECRB
 - Radial recurrent vessels (leash of Henry)

- Radiocapitellar joint capsule and osteophytes
- Supinator distal edge

PATHOGENESIS

- Compression of the radial nerve, PIN, or SBRN by one or more anatomic structures at the radial tunnel, which can be secondary to aberrant anatomy, mass effect, trauma, arthrosis, or idiopathic
- Pathogenesis and pathophysiology of RTS is poorly understood and controversial owing to the fact that it is a compressive neuropathic pain syndrome with no reliably identifiable motor, radiologic, or electrodiagnostic findings.
- Although the PIN is a motor nerve, it does contain group IIA and IV fibers, which have been associated with temperature and nociception.⁷ Given that these are not evaluated in standard electrodiagnostic testing, one possibility is that they may contribute to the pain syndrome even though nerve conduction velocities remain normal.
- Occupations that require heavy tool use in full elbow extension have been identified as a risk factor for development of RTS.^{8,9}

PATIENT HISTORY AND PHYSICAL FINDINGS

- History
 - Patients complain of pain and fatigue in the proximal dorsal forearm.
 - Pain may radiate and can be aggravated by activities loading a rotated forearm or extended wrist.¹
 - Muscle weakness is either absent or secondary to pain.¹⁰
 - Sensory disturbances are usually absent.
- Physical exam
 - The primary finding is localized tenderness over the radial nerve 5 cm distal to the lateral epicondyle.¹¹
 - Provocative tests include pain with resisted forearm supination and/or resisted active extension of the middle finger.¹⁰
 - The “rule of nines” test has been proposed to help localize tenderness to the radial tunnel and help differentiate from other nearby sources of pain. In this test, the proximal volar forearm is divided into nine squares and tenderness with the lateral column marking out the radial tunnel.¹²
 - Examination must take into consideration several other possible sources of proximal forearm pain, especially lateral epicondylar tendinopathy, in which

tenderness is located more proximally over the epicondyle.

- **Electrodiagnostic studies**
 - The results of standard nerve conduction velocity (NCV) and electromyography (EMG) studies are typically normal.
 - Although several modifications to standard NCV testing have been proposed, including testing latencies in different forearm positions and testing motor latencies to different motor groups, these have not been widely adopted in clinical practice.^{13,14}
 - Electrodiagnostic studies may be useful to help rule out cervical radiculopathy or other concomitant entrapment neuropathy.

IMAGING

- Plain radiographs are typically nondiagnostic for RTS but can identify radiocapitellar arthrosis, which can lead to a distended, synovitic joint capsule and extrinsic compression at the radial tunnel.
- Magnetic resonance imaging (MRI) is not routinely helpful in the diagnosis of RTS. One study comparing MRI in 25 patients with RTS found that 52% had either edema or denervation atrophy of the supinator, whereas 28% had other aberrant anatomy such as nerve swelling, thickened ECRB, or prominent recurrent vessels.¹⁵
- The combination of the patient's history, physical exam, and MRI can also help to delineate radial tunnel from lateral epicondylar tendinopathy.

DIFFERENTIAL DIAGNOSIS

- Radial tunnel syndrome
- Lateral epicondylar tendinopathy
- PIN syndrome
- Cervical radiculopathy
- Biceps tendinitis or local muscle strain
- Osteoarthritis of the radiocapitellar joint
- Synovial impingement of the elbow
- Wartenberg syndrome

NONOPERATIVE MANAGEMENT

- Nonoperative treatment using anti-inflammatories, splinting, and activity modification should be exhausted prior to consideration of operative treatment and may lead to resolution of symptoms.¹⁶

- Although evidence for steroid injections is limited to a single small trial, it may be considered for patients with ongoing symptoms who are poor surgical candidates or those who do not want to consider surgery.¹⁷
- When a local anesthetic is mixed with the steroid injection, this can serve as a diagnostic aid and is considered successful if both pain symptoms are temporarily alleviated and a motor block of the PIN is achieved.

SURGICAL MANAGEMENT

- Operative radial nerve decompression is indicated for those patients who have failed to improve after prolonged nonoperative treatment.
- Intravenous regional (Bier block) and axillary block regional are preferred methods of anesthesia.
- Three commonly described dorsal surgical approaches to release potential compression points along the radial tunnel have been described.
 - ECRB-extensor digitorum communis (EDC) interval
 - ECRL-BR interval
 - BR transmuscular splitting approach
- The authors prefer the ECRL-BR interval for the following reasons:
 - It avoids muscle splitting.
 - It allows for easy identification of the radial nerve, PIN, and the sensory branch of the radial nerve to ensure all are free from compression.
 - There is some evidence to support more reliably successful outcomes with decompression of the SBRN, which is best addressed through this interval.^{18–20}
 - The most common complication of radial tunnel decompression is neuropraxia of the SBRN, which is best identified and protected in this interval.^{20–23}
 - The interval is easily identifiable when marked out in the preoperative area by having the patient flex the elbow against resistance.

TECHNIQUES

■ **Radial Tunnel Decompression**

Exposure

- In the preoperative area, ask the patient to flex the elbow against resistance to help mark out the interval between BR and ECRL.
 - This causes brachioradialis (BR) to become prominent while the extensor carpi radialis longus (ECRL) is relaxed, making the interval much easier to locate.
- A straight longitudinal or lazy-S incision is made through the skin and dermis (**TECH FIG 1A**).
- Care is taken to identify and protect the posterior cutaneous nerve of the forearm and any posterior branches of the lateral antebrachial cutaneous nerve.
- The fascia overlying BR and ECRL is incised and the interval is developed (**TECH FIG 1B**).
 - BR fascia is thinner, and thus, the BR muscle belly will appear as a brighter red color.
 - The dorsal ulnar edge of BR is also thinner, coming to a tapered edge and lying superficial to the more dorsal central aspect of the ECRL.
 - This interval should open easily and with mostly blunt dissection. If extensive sharp dissection is required, the surgeon has likely strayed out of the appropriate interval.

Release of Entrapment

- Coming down between BR and ECRL will bring the surgeon to a layer of fat containing the SBRN.

TECH FIG 1 • **A.** Proposed incision over the dorsal proximal forearm marked out at interval between brachioradialis and extensor carpi radialis longus. **B.** Superficial interval between brachioradialis (BR) and extensor carpi radialis longus (ECRL). Note the

thinner edge of BR and the more rounded, dorsal central aspect of ECRL.

TECH FIG 2 • A. Intermediate interval between extensor carpi radialis longus (ECRL) and extensor carpi radialis brevis (ECRB) ulnarly and brachioradialis (BR) radially. The radial recurrent vessels (leash of Henry) course through and over the radial nerve branches (PIN, SBRN, nerve to ECRB). **B.** Deep interval after limited external neurolysis of radial nerve branches, ligation of crossing vessels, and release of proximal edge ECRB reveals the tight, tendinous leading edge of supinator (arcade of Frohse) directly compressing the PIN. **C.** Release of

the supinator reveals a chronic compression deformity of the PIN. (For all parts, proximal is to the left, distal to the right, radial to the top, and ulnar to the bottom.)

- Follow the SBRN proximal, and you will encounter the radial recurrent vessels (leash of Henry) (**TECH FIG 2A**).
 - They must be ligated with suture or clips.
 - Dissecting more proximally within this interval, follow the SBRN and you will encounter the posterior interosseous nerve (PIN) and the nerve to extensor carpi radialis brevis (ECRB).
 - Meticulous care to dissect and control crossing vessels is essential.
 - Release any constricting fascial bands over the SBRN as this may increase the likelihood of success.^{18–20}
 - At this point, you will have identified the SBRN, nerve to ECRB, and the PIN (**TECH FIG 2B**).
 - From radial to ulnar, the orientation will be SBRN, nerve to ECRB, and PIN.
 - The PIN will be larger in caliber and coursing distal and ulnar.
 - The SBRN and nerve to ECRB will be parallel to one another.
 - Follow the PIN distally and release the overlying ECRB fascia, which can be a point of compression.
 - After ECRB fascia has been released, you will encounter the supinator fascia (arcade of Frohse), which must be released (**TECH FIG 2C**).
 - As ECRB has been implicated in lateral epicondylar tendinopathy, release of the ECRB tendon may be helpful for patients with concomitant “tennis elbow.”
 - Check proximally and distally to ensure no further entrapment points exist.
 - Proximally, fibrous bands over the radial head can sometimes be found.
 - If used, the tourniquet is released to ensure adequate hemostasis.
 - Close the skin using a dermal layer with 4-0 absorbable suture followed by a subcuticular layer using 4-0 absorbable suture.
 - A long-arm, soft bulky dressing is applied using a thin layer of gauze, sterile cast padding, and a very lightly compressive wrap.
-

PEARLS AND PITFALLS

Preoperative marking	■ Marking out the BR-ECRL interval in the preoperative holding area with the patient flexing the elbow against resistance can make surgical orientation much easier.
Hemostasis	■ Meticulous care to control crossing vessels throughout the case is a part of the decompression, can save time when the tourniquet is let down, and will prevent postoperative hematoma formation.
Adequate exposure	■ A minimal exposure can lead to inadequate visualization of all compression points and necessitate excessive retraction on the muscular interval, as well as the SBRN, leading to known complications.
Decompression of all radial nerve branches	■ External neurolysis of the radial nerve, nerve to ECRB, PIN, and SBRN is important to maximize likelihood of success.

POSTOPERATIVE CARE

- Immediate active digital, wrist, and forearm motion is allowed, but with limited weight bearing until the 2-week clinic follow-up.
- The dressing is removed 2 days after surgery.
- The wound is checked and any external sutures are removed at 2 weeks.
- Strengthening allowed at 3 weeks and patients are expected to be back to normal work activities by weeks 4 to 6.

OUTCOMES

- No level 1 evidence exists to guide expected outcomes following radial tunnel release.
- Patients who have had “successful” outcomes following radial tunnel release varies widely in the literature from 32% to 97%^{19,21,22} prompting controversy as to the effectiveness of the procedure.
- Known risk factors that lower expected success rates of radial tunnel decompression include
 - Concomitant lateral epicondylitis²²
 - Multiple entrapment neuropathies²²
 - Workers compensation/litigation²²

- A recent study by Lee and colleagues found good results in 86% of patients with isolated RTS, whereas this number dropped to 57% in patients with multiple entrapment neuropathies and 40% in patients with associated lateral epicondylar tendinopathy.²²
- A thorough examination of available literature makes it clear that appropriate patient selection based on clinical history, exam, and diagnostic workup is crucial to success in the treatment of RTS.

COMPLICATIONS

- Complication rates have been reported in a portion of available retrospective reviews and case series; however, the anticipated rate of these complications is difficult to determine.
- Some reported complications include
 - SBRN neurapraxia or hyperaesthesias^{20–22}
 - Paresis of common digital extensors^{21,23}
 - Postoperative hematoma²¹
 - Complex regional pain syndrome²⁰
 - Infection²⁰

Primary Nerve Repair and Nerve Graft for Traumatic Nerve Injuries

30

CHAPTER

Sonya Paisley Agnew and Jason H. Ko

DEFINITION

- In the setting of acute nerve injuries, the surgeon should abide by the following principles when performing a nerve repair or reconstruction:
 - Debridement of the injured nerve ends to healthy fascicles
 - Correct alignment of fascicles when possible
 - Delicate handling of neural tissue
 - Tension-free repair or reconstruction
 - Prevention of fascicular outgrowth at the coaptation site
- The level of injury, zone of injury, primary nerve function (motor vs sensory), and functional significance of the injured nerve (eg, “critical” nerves such as the ulnar digital nerve to the thumb vs “noncritical” nerves such as the ulnar digital nerve to the long finger) will guide choice of treatment.
- Options for repair include primary repair with or without a conduit vs reconstruction with nerve grafts (autograft vs allograft).¹ Consideration should be given to techniques for bolstering the nerve coaptations (eg, fibrin glue, nerve wraps, nerve tubes).
- The most commonly used techniques for nerve coaptation are an “epineurial repair,” which is suturing of the epineurium with no direct manipulation of the fascicles, and a “grouped fascicular repair,” which requires reorienting the fascicles and directly placing sutures into the perineurium of the fascicles (**FIG 1**).
- No studies have documented superiority of one coaptation technique over the other.

ANATOMY

- An understanding of fascicular anatomy of mixed major peripheral nerves can improve the outcomes of nerve repair by aligning proximal fascicles with their distal targets—matching proximal motor fascicles to distal motor fascicles and proximal sensory fascicles to distal sensory fascicles, whenever possible.
- This topographical orientation has been described for major mixed nerves, including the median and ulnar nerves, which can help with fascicular alignment when treating lacerations at various levels in the forearm and hand.²
- Anatomic fascicular orientations that have been well-established in the literature¹:
 - Median nerve in the forearm (**FIG 2**)
 - The motor branches lie peripherally (in the radial and ulnar aspects of the median nerve), with sensory fascicles located centrally. The recurrent motor fascicle is a separate, distinct fascicle 10 cm proximal to the radial styloid and located radially.
 - Median nerve at the wrist level (see **FIG 2**)
 - Recurrent motor fascicles are located within the volar and radial aspect of the nerve.
 - Digital sensory fascicles are located dorsally along both the radial and ulnar aspects of the nerve.
 - The ulnar nerve in the forearm (see **FIG 2**)

FIG 1 • Nerve coaptation techniques. **A.** Epineurial repair. **B.** Grouped fascicular repair.

FIG 2 • Intraneural topography of the median nerves at various levels.

- Dorsal sensory branch of the ulnar nerve is located in an ulnar position within the nerve and separates from the main nerve 5 to 8 cm proximal to the radial styloid.
 - The intrinsic motor fascicles lie dorsal to the digital sensory fascicles and are distinct 9 cm proximal to the ulnar styloid.
 - In the proximal forearm, the motor fascicles (intrinsic and flexor carpi ulnaris [FCU]/flexor digitorum profundus [FDP]) are centrally located, and the sensory fascicles are superficial.
 - At the wrist level, the ulnar nerve motor branch is dorsal and ulnar relative to the sensory fascicles—the motor fascicles can be seen as separate and distinct up to 9 cm proximal to the ulnar styloid.³
- Grouped fascicular repair should be used in larger mixed nerves, such as the median nerve at the humeral level.³
 - Care should be taken to avoid bulky perineurial sutures that may become an obstacle to axonal regrowth.

- The less the ends of the nerve are manipulated intraoperatively, the less scarring there will be at the coaptation site.
- Microsutures should be used to repair the epineurium for all nerve repairs. The coaptation sites can be augmented with fibrin glue at the discretion of the surgeon.
- Tension should be avoided at all cost when performing a nerve coaptation. In the authors' opinion, rather than repairing a nerve under tension, the surgeon should reconstruct the nerve with an interpositional nerve graft (autograft or allograft) to achieve a tension-free construct.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Physical exam:
 - A thorough motor examination and evaluation of sensation by two-point discrimination or Semmes-Weinstein monofilament testing will help to localize the nerve injury and adequately counsel the patient regarding postoperative expectations.
 - The location of a Tinel sign will help to pinpoint the site of nerve injury in the acute setting, and an advancing Tinel sign can be used to measure nerve regeneration over time.
 - In the acute setting, the sensory examination may be unreliable due to pain or neurapraxia.
- History: When obtaining the patient's history, certain factors are important for preoperative planning and counseling, including the following:
 - Patient age: Nerve regeneration occurs more rapidly in younger patients. The potential for nerve recovery decreases with age and should be addressed preoperatively with the patient. Older individuals are more likely to have delayed and/or incomplete recovery.
 - Chronicity of injury: In a delayed nerve repair, the surgeon should be prepared for retraction of the proximal nerve stump, in addition to neuroma formation, which may necessitate the use of nerve grafts.

IMAGING

- Ultrasound may be helpful in determining the presence of neuroma-in-continuity or complete laceration of the nerve. It offers the advantage of allowing static and dynamic assessments of the nerve and associated structures.
- MR neurography can also be used to evaluate larger nerves, but it is less effective at visualizing smaller nerves in the palm and fingers.

- Other imaging modalities are not commonly used for traumatic nerve injuries. Operative exploration is the primary method of diagnosis and treatment.

SURGICAL MANAGEMENT

Preoperative Planning

- The patients should be monitored closely to determine the extent of peripheral nerve injury.
 - A penetrating injury with acute nerve deficit warrants operative exploration.
 - A blunt or closed injury with acute nerve deficit may justify a period of monitoring to rule out neurapraxic injury.
- Sharp injury: If addressed acutely, primary nerve repair is possible. Nerve wraps or conduits can be used as adjuncts, if there is minimal tension at the repair site. If primary repair is under tension, then interpositional nerve graft should be used for reconstruction instead.
- Crush injury: The surgeon should be prepared for a broad zone of injury with extensive injury to the nerve. Nerve grafting will most likely be necessary, and the surgeon should consider delayed repair so that the zone of injury in the nerve can be better assessed as the soft tissue heals.
- Poor soft tissue cover: It is important for the surgeon to perform local or distant soft tissue flaps to achieve a stable, well-vascularized soft tissue envelope over the site of a nerve injury. Stable overlying soft tissue is a prerequisite for successful nerve repair or reconstruction.
- Timing: Neuromuscular function disappears 3 to 5 days after nerve transection,⁴ whereas nerve action potentials remain for 7 to 9 days after injury.⁵ After this time period, the use of intraoperative stimulation to aid in fascicular identification is not possible.

Positioning

- Supine positioning
- For distal nerve injuries in the upper extremity, a well-padded tourniquet is placed on the proximal arm.
 - The authors recommend tourniquet use to maintain a bloodless field, which will more easily identify peripheral nerves, especially in the setting of substantial scarring.
 - However, if intraoperative motor nerve stimulation will be performed, the tourniquet should be released within 30 to 40 minutes to avoid tourniquet

neurapraxia.

- The hand table should have a stable base to limit motion during microsurgery.
- If sural nerve grafts are indicated, one or both legs are circumferentially prepared, and a thigh tourniquet should be used. It may be beneficial to harvest the sural nerve from the contralateral leg, which allows a bump to be placed under the contralateral hip.

Approach

- Bruner incisions to cross wrist and digital creases are employed to avoid straight-line incisions across joints.
- For sural nerve harvest, stair-step incisions may be used to decrease the overall length of the harvest site (**FIG 3**). However, longitudinal incisions directly over the entire length of sural nerve can be performed. Endoscopic sural nerve harvest techniques can also be employed.
- Nerve repair and reconstruction requires identification of injured nerve ends. Bruner or mid-lateral incisions should be used to expose the injured nerve(s) on the volar aspect of the palm or fingers. Bruner extensions should be used across all volar joint creases in the upper extremity. Dorsally, longitudinal incisions can be made over joint surfaces.
- Tenotomy scissors should be used to dissect the proximal and distal ends of the injured nerve(s) as atraumatically as possible. Overlying fascia or compression points should be released for better mobilization of the nerve ends.

FIG 3 • A,B. Stair-step sural nerve harvest.

TECHNIQUES

■ Primary Nerve Repair

- A direct repair is indicated in a sharp laceration when the nerve ends may be brought together with no tension.
 - Traumatized fascicles should be sharply debrided to healthy-appearing ends and oriented (in cases of larger nerves) appropriately.
 - If the nerve ends cannot be approximated without any tension, direct nerve repair should not be performed—nerve grafting should be used instead.
 - If nearby joints (eg, fingers, wrist, elbow) have to be flexed down to help minimize tension on the nerve repair, the primary nerve repair is too tight and should be abandoned.
- Lining up epineurial vessels proximally and distally can be used to help with orientation at the time of nerve repair. This will make pairing up the proximal and distal fascicles easier.
- Use of an operating microscope is recommended,⁶ and 8-0 or 9-0 nonabsorbable monofilament suture should be used for epineurial repair to orient proximal fascicles to their distal targets (**TECH FIG 1A–F**)
- Fascicles that are “outpouching” should be tucked into the epineurial repair and trimmed back if necessary (**TECH FIG 1G,H**).
- A piece of surgical glove, Esmarch bandage, or silicone background can be used like a “burrito” to wrap around the repair into which fibrin glue is applied to bolster the repair. After the fibrin glue has set, the burrito wrap is removed.
- At this point, the surgeon should consider releasing any potential distal compression points (eg, the transverse carpal ligament distal to a median nerve repair in the distal forearm; Guyon canal release after an ulnar nerve repair at the wrist).

TECH FIG 1 • Ulnar nerve repair proximal to the elbow. Anterior transposition can be performed to reduce tension on the nerve coaptation. **A.** Gunshot wound with suspected ulnar nerve injury. Dotted marks outline possible incision location. **B.** Exploration

reveals a complete ulnar nerve transection proximal to the elbow. **C.** Anterior transposition of the ulnar nerve has been performed by extending the skin incision distally and completely releasing the ulnar nerve from the cubital tunnel. **D.** Anterior transposition of the ulnar nerve allows for tension-free primary nerve coaptation. **E.** Fascial sling of the flexor-pronator was elevated sharply anterior to the medial epicondyle. **F.** The fascial sling is sutured to the deep surface of the anterior skin flap. **G.** Outpouching of the fascicles should be avoided to prevent aberrant axonal regeneration. **H.** The fascicles should be trimmed and aligned to maximize regeneration.

■ Repair in the Setting of a Small Nerve Gap in a Small Caliber Nerve

- When the ends of a nerve cannot be brought together without tension despite proximal and distal mobilization, use of a nerve graft is indicated.
- For digital nerve gaps, lateral antebrachial cutaneous (LABC) nerve, medial antebrachial cutaneous (MABC) nerve, and posterior interosseous nerve (PIN) are suitable sizes for autograft (**TECH FIG 2**). These have the additional benefit of using a donor site in the same surgical area as the nerve reconstruction.
- Alternatively, processed nerve allograft (PNA) of varying lengths and diameters are available as an off-the-shelf option with no donor site concerns (**TECH FIG 3**).
- The proximal and distal ends of both repair sites can be bolstered with absorbable polyglycolic nerve tubes, fibrin glue, or xenogenic wraps (**TECH FIG 4**).

TECH FIG 2 • Posterior interosseous nerve harvest in the dorsal wrist. **A.** Incision site. **B.** Isolation of nerve.

TECH FIG 3 • **A.** A 5-cm nerve gap in the median nerve at the level of the carpal tunnel. **B.** Repair with processed nerve allograft.

TECH FIG 4 • Direct digital nerve repair (A) and after wrapping with xenogenic nerve wrap (B).

■ Repair of Larger Nerve Gaps or Larger Caliber Nerves

- When a large gap in a nerve exists, either cable grafts or processed nerve allografts are indicated.

Sural Nerve Harvest Technique

- The sural nerve can be harvested in the supine position with a well-padded sterile tourniquet on thigh and the knee flexed.
 - A sterile sandbag and/or an assistant can keep the knee flexed and hip internally rotated.
- If a single sural nerve is to be used, harvesting the contralateral sural nerve will allow a bump or pillows to be placed under the contralateral hip to help gain better access to the posterolateral aspect of the leg, especially more proximally where the sural nerve is deeper.
- If bilateral sural nerves must be harvested, the surgeon should consider performing the sural nerve harvest in the prone position, which would most likely require an intraoperative position change to access the upper extremity.
- Surface landmarks for sural nerve harvest—the lateral malleolus and anterior edge of the Achilles tendon—are marked.

- **FIG 3** depicts the step-cut technique for sural nerve harvesting.
 - The sural nerve is easily located 2 cm superior and posterior to the lateral malleolus. Distal to the malleolus, the nerve begins to branch and becomes significantly smaller.
 - The lesser saphenous vein is intimately associated with the nerve and can be protected or ligated.
 - Gentle traction is placed on the nerve to determine the more proximal incisions.
 - The intervening skin bridges should be short enough that undue traction is not necessary to free the nerve from the surrounding soft tissue.
- The dissection proceeds proximally to the junction of the medial and lateral sural nerves in the mid-leg, where the medial branch pierces the gastrocnemius fascia, and the lateral sural nerve continues superficially.
 - The dissection can continue easily toward the origin of the lateral sural nerve from the common peroneal nerve or the medial sural nerve in between the two heads of the gastrocnemius muscle.⁷
- Approximately 30 cm of sural nerve can be harvested from one leg.
- A suture or surgical marking pen can be used to signify the proximal end so that the graft is reversed when brought to the recipient site.
 - Graft reversal prevents theoretical loss of axonal regeneration down small side branches and into surrounding soft tissues.

Graft Preparation

- For large defects, multiple sural cables should be prepared, and the number used depends on the number of large groups of fascicles within the injured nerve, in addition to the total length of sural nerve harvested.
- The nearby joints (fingers, wrist, elbow) should be maximally extended when measuring the nerve graft and length of nerve graft needed.
 - This will allow the nerve graft to be placed under no tension, even with early postoperative motion.
- After the length of the nerve defect is measured, the number of cables required is determined by the number of larger groups of fascicles visible that can be matched to accept individual grafts.
- The cables are brought together on a separate operating room table and rolled into a “burrito” as referenced earlier, followed by augmentation with fibrin glue.
 - This technique has been referred to as the “super nerve” technique (**TECH**

FIG 5A,B).

- The ends are sharply transected, exposing the grouped fascicles, and one end is coapted to the proximal recipient nerve defect with 8-0 or 9-0 nonabsorbable monofilament suture with the aid of an operating microscope.
- Identical preparation is done for the distal end of the cable graft, and the graft is inset in a similar fashion to the distal recipient nerve (**TECH FIG 5C,D**).
- The central portion of the cable graft is gently draped into the soft tissues with space between the cables to allow for revascularization.
- The upper extremity is taken through a full range of motion to verify that the nerve reconstruction is under no tension.

TECH FIG 5 • A,B. Preparation of multiple sural nerve cable grafts on the back table prior to reconstruction—the “super nerve” technique. **C,D.** Ulnar and median nerves grafted with sural nerve cable grafts.

Nerve gap	■ Avoid tension and have low threshold to perform nerve grafting.
Fascicular orientation	■ When possible, align fascicles at the time of repair.
Positioning	■ Repair and grafts should be tensioned to allow for “safe” positioning of the fingers/wrist/digits. Flexed postures to accommodate primary repair should be avoided at all costs. When in doubt, use a graft.

POSTOPERATIVE CARE

- For direct nerve repairs, splinting in a position that keeps the nerve repair under no tension should be considered for 2 weeks.
- For nerve reconstructions under no tension, splinting for 2 weeks is optional. A soft dressing is recommended when there is no tension.
- If immobilization is used, range of motion (ROM) begins at 2 weeks.
- Nerve regeneration begins after a period of 30 days and from this point on continues at a rate of 1 mm/d, 1 in./mo, and 1 ft./y.
 - The surgeon should follow the patient for signs of distally migrating sensory recovery and strength testing for motor reinnervation.
- Based on the distance from repair site to distal nerve endings, the surgeon can calculate at what point the patient should begin to experience noticeable recovery, and follow the Tinel sign along the path of the nerve.
 - If the Tinel sign ceases to cross the repair site, consideration should be given to repeat exploration, neurolysis, possible neuroma excision, and grafting.

OUTCOMES

- Positive predictors of sensory recovery include age and time since repair, and data show trends consistent with better outcomes for sharp injuries.
- There is no association between delay in repair and outcome for sensory injuries.⁸
 - For mixed nerve injuries, time to repair is critical as the motor endplates will cease to function after 18 to 24 months, and worse outcomes are seen after a delay in repair of more than 6 to 12 months.⁹
- Similarly, the distance from the injury to the target muscle is an important determinant of outcome.
 - The surgeon may calculate the distance from the injury from the target muscle and determine the time it will take for reinnervation to commence.

- A commonly reported “satisfactory” result is seen as recovery of M4 (active movement against resistance) or M5 (full power) for motor, and sensation S3+ (static two-point discrimination of 7–11 mm).¹⁰
- When grafting is required, the results of allograft and autograft nerve appear at this time to be equivalent.

COMPLICATIONS

- Complications of nerve repair are primarily inadequate recovery of sensation or motor function and neuroma formation.
- For inadequate sensory recovery, exploration with neurolysis and possible neuroma excision and grafting may be indicated, although there is no urgency to perform this.
- For suboptimal recovery of motor function, either nerve or tendon transfers may be indicated depending on the nerve injured and the time since injury.

31 Tendon Transfers for Median Nerve Injury

CHAPTER

Rafael J. Diaz-Garcia and Kevin C. Chung

DEFINITION

- Median nerve palsy refers to the loss of motor control and sensation of the hand in the distribution of the median nerve.
- Low median nerve palsy refers to the loss of motor control and sensation of the hand in the distribution of the median nerve. Loss of sensation is the greatest deficit, because it encompasses 70% of the palmar surface. Loss of thenar function, particularly opposition, warrants reconstruction consideration.
- High median nerve palsy has significantly greater disability than does low median palsy due to the variable loss of function in the forearm, which can include pronation and flexion of the thumb, index, and long fingers.

ANATOMY

- The median nerve is a mixed nerve composed of fibers from the C5 through T1 roots, forming as a confluence of the lateral and medial cords of the brachial plexus.
- It travels with the brachial artery in the upper arm, between the biceps brachii and brachialis. It crosses anteriorly to the vessel as it reaches the antecubital fossa. It enters the forearm between the two heads of the pronator teres, innervating it.
- The median nerve travels between the flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) in the forearm. It gives off a branch, the anterior interosseous nerve, to innervate the flexor pollicis longus, the radial ½ of FDP, and pronator quadratus.
- The median nerve proper innervates the flexor carpi radialis, FDS, and palmaris longus.

- The palmar cutaneous branch arises 5 cm proximal to the wrist joint, supplying the skin of the thenar eminence.
- The median nerve passes superficially in the carpal tunnel, before giving the recurrent motor branch from the central or radial portion of the nerve. It usually passes distal to the transverse carpal ligament. It passes through the transverse carpal ligament up to 7% of the time.¹ The motor branch goes to the opponens pollicis, abductor pollicis, and the superficial head of the flexor pollicis brevis.
- The sensory branches provide sensation to the radial 3½ digits of the hand.
- Martin-Gruber and Riche-Cannieu connections represent anomalous innervation patterns between the median and ulnar nerves, which may complicate the findings on exam.

PATHOGENESIS

- The pathogenesis of median nerve palsy is most frequently due to compression, attributed usually to long-standing carpal tunnel syndrome.
- Median nerve lacerations happen most commonly at the wrist due to the superficial position of the nerve.
- Lipofibromatoma of the median nerve can be seen in pediatric cases.²
- Systemic conditions such as Charcot-Marie-Tooth disease can also cause median neuropathy.³
- The pathogenesis of high median nerve palsy is most frequently caused by trauma, which can happen from injuries extending from the brachial plexus to the forearm.
- Compression can also cause high median nerve palsy, though it is much more frequently the cause of low median nerve palsy. Sites of proximal compression include the pronator teres, lacertus fibrosis, and supracondylar process.

NATURAL HISTORY

- Compressive causes can have insidious onset symptoms over the period of years or even decades.
- Traumatic cases have a clearer history because of the abrupt onset of sensory disturbance that is noticed by the patient.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Acute injury
 - Patients present with a history of trauma and often a laceration, usually in the

volar wrist.

- Patients present with diminished sensation in the radial 3½ digits of the hand and a positive Tinel sign at the level of injury. There is greater functional loss with high median nerve palsy. There is a loss of opposition, flexion of the thumb through long fingers, and potentially pronation.
- Palmar abduction may still be present from the intact abductor pollicis longus.
- Chronic compression
 - Patients present with pain, numbness, and paresthesias of the radial 3½ digits.
 - In carpal tunnel syndrome, symptoms may be exacerbated during sleep or activities that require wrist flexion, such as driving or keyboard use.
 - They often complain of “clumsiness” or difficulty with fine motor functions.
 - The most notable finding on physical exam in long-standing low median palsy is thenar atrophy.
 - In pronator syndrome, symptoms may be exacerbated with compression of the proximal forearm over the pronator teres.
- Inability to make an “OK” sign with the thumb and index finger reflects pathology involving the anterior interosseous nerve.
- Lack of pronation reflects pathology proximal to the elbow

IMAGING

- Initial workup for acute median nerve palsy may warrant x-rays to determine if there are any fractures or dislocations in the extremity associated with the acute trauma.
- Nerve conduction studies and electromyography may be helpful in the workup of compressive median neuropathy, helping to determine the level of the lesion.
- Motor and sensory latencies are often increased with chronic compression of the median nerve. Fibrillation potentials indicate denervation of the muscles tested and axonal loss.
- MRI of the brachial plexus may be warranted if there is concern for a lesion at this level.

DIFFERENTIAL DIAGNOSIS

- Carpal tunnel syndrome
- Isolated median nerve injury
- Anterior interosseous syndrome
- Pronator syndrome

- Cervical radiculopathy
- Leprosy
- Charcot-Marie-Tooth disease
- Brachial plexus lesion

NONOPERATIVE MANAGEMENT

- Nonoperative management is indicated in the setting of a brachial neuritis (Parsonage-Turner syndrome), presenting with anterior interosseous nerve dysfunction.
- Work modification may be warranted in a patient with compressive neuropathy secondary to over use in pronator syndrome.
- Thumb adduction contractures must be prevented or treated prior to tendon transfers, as maximum passive motion must be acquired before any tendon transfers.

SURGICAL MANAGEMENT

- There are three key functions that tendon transfers must address in the setting of high median nerve palsy:^{9,10}
 - Thumb opposition
 - Flexion of the thumb
 - Flexion of the index and long fingers
- Occasionally, lack of pronation may require biceps rerouting. However, shoulder abduction can often compensate for this deficit enough to not be an issue.
- Unlike nerve transfers, tendon transfers do not have a firm time period in which they must be performed. Tendon transfers can be delayed while awaiting potential nerve recovery.
- The common principles of tendon transfers are as follows:
 - Joint contractures should be treated prior to any transfers.
 - Each muscle transfer should target one specific function.
 - Transferred tendons should glide through a smooth and scar-free surgical site.
- Thumb opposition cannot be reconstructed using FDS or palmaris longus in the setting of high median nerve palsy, as it would be in low median nerve palsy. Examination should be able to determine whether these muscles are functional.⁸
- In isolated low median nerve palsy, all reconstruction options are available. In

general, using the extensor indicis proprius is our first choice given the negligible donor morbidity and excellent tendon excursion. The Camitz transfer (palmaris longus) is a good option for elderly patients with long-standing carpal tunnel syndrome. It is simple to execute at the time of carpal tunnel release but creates more palmar abduction than true opposition. The Huber transfer (abductor digiti minimi) is reserved for children and for combined high median and radial nerve palsies.

Preoperative Planning

- Tendon transfers should be delayed until after potential nerve recovery is completed.
- Clinical exam of the patient will allow the surgeon to decide what functions must be recreated and what donor muscles are available for each function.

Positioning

- The patient is placed in the supine position with a tourniquet on the upper arm.
- The OR lights are positioned with one projecting from proximally and one distally from the operative site.

Approach

- Like with all tendon transfers, one should plan for the tendons to glide through a smooth and scar-free wound bed and each transfer should be for one function. If there is scarred tissue along the path of the transfer, it must be replaced by soft supple tissue either through serial scar excision or a flap procedure.

TECHNIQUES

■ Low Median Nerve Injury: Reconstruction of Thumb Opposition

Palmaris Longus to Abductor Pollicis Brevis (Camitz Transfer)

- Confirm the presence of a palmaris longus (PL) tendon and design a longitudinal incision, from the distal wrist crease to the proximal palmar crease, with a Bruner design over the wrist joint (**TECH FIG 1A**).
- Dissect the palmaris longus distally, taking a patch of palmar aponeurosis

along with the tendon (**TECH FIG 1B**).

- Make an incision over the dorsoradial aspect of the thumb metacarpophalangeal (MCP) joint.
- Create a subcutaneous tunnel between the PL tendon and the MCP joint with blunt dissection.
- Pass the PL tendon to the thumb incision and suture it to the abductor pollicis brevis (APB) tendon (**TECH FIG 1C,D**) and extensor hood.

Flexor Digitorum Superficialis to Abductor Pollicis Brevis (Bunnell Transfer)

- A transverse incision is made over the ring finger A1 pulley (**TECH FIG 2A**).
- The A1 pulley is exposed and divided longitudinally, preserving the neurovascular bundles.
- The flexor digitorum superficialis (FDS) is divided proximally to the bifurcation with proximal longitudinal traction.
- A Bruner or longitudinal incision is made over the ulnar wrist, just radial to the flexor carpi ulnaris (FCU) tendon and near its insertion.

TECH FIG 1 • A. Design of incisions for PL transfer to AP. **B.** Exposure of PL at insertion into palmar fascia. **C.** PL tendon is sutured to APB, creating palmar abduction. **D.** PL tendon is sutured to APB, creating palmar abduction.

TECH FIG 2 • A. Tendon anatomy for FDS to APB (Bunnell) transfer. **B.** Looping of the FCU tendon to create a pulley for transfer. **C.** Passage of FDS tendon through the FCU pulley for suture to the APB tendon.

- The radial half of the FCU tendon is divided and separated from the ulnar half longitudinally.
- The distally based FCU tendon is sutured to itself at the insertion site, creating a pulley (**TECH FIG 2B**).
- A longitudinal incision is made along the radial aspect of the thumb MCP

joint.

- A subcutaneous tunnel is created from the thumb incision to the wrist incision.
- The FDS is passed through this pulley and then through the tunnel to the thumb, where it is sutured to the APB tendon and extensor hood with braided suture (**TECH FIG 2C**).

Abductor Digiti Minimi to Abductor Pollicis Brevis (Huber Transfer)

- A Bruner or curvilinear incision is made from the ulnar aspect of the small finger to the radial border of the hypothenar eminence (**TECH FIG 3A**).
- The abductor digiti minimi (ADM) is dissected distally, protecting the ulnar neurovascular bundle to the small finger. It is freed from the underlying flexor digiti minimi, if present (**TECH FIG 3B**).
- The ADM is released from its insertion site on the small finger proximal phalanx with a portion of the lateral band to increase its length.
- From distal to proximal, mobilize the muscle toward and eventually off of the pisiform. Preserve the neurovascular bundle, which comes from the deep and radial surface of the muscle (**TECH FIG 3C**).
- Make an incision along the radial aspect of the thumb MCP joint and use blunt dissection to create a subcutaneous tunnel in the palm, superficial to the transverse carpal ligament.
- Pass the ADM through the tunnel to the thumb and suture it to the APB tendon and extensor hood with permanent braided suture (**TECH FIG 3D**).

TECH FIG 3 • **A.** Design of incisions for ADM transfer to APB. **B.** Exposure of ADM along hypothenar eminence. **C.** Dissected free ADM muscle, all the way to pisiform. **D.** Final position after transfer, creating both palmar abduction and opposition.

■ High Median Nerve Injury

Reconstruction of Thumb Opposition: Extensor Indicis Proprius to Abductor Pollicis Brevis

- A small longitudinal incision is made along the dorsoulnar aspect of the index MCP joint (**TECH FIG 4A**).
- The extensor indicis proprius (EIP) tendon is identified as the ulnar tendon and released from the index finger extensor hood with a small slip of extensor mechanism. The rent is repaired with permanent suture.
- A longitudinal incision is made over the dorsoulnar wrist, just proximal to the ulnar styloid.
- Dissection is carried radially from this wrist incision to find the EIP tendon, just distal to the extensor retinaculum. The distal aspect of the fourth extensor compartment is divided to fully mobilize the tendon.
- A small incision is made along the radial pisiform and a longitudinal incision along the radial aspect of the thumb MCP (**TECH FIG 4B**).

- A subcutaneous tunnel is created from the dorsal wrist incision to the pisiform incision, attempting to stay deep to the ulnar sensory nerve branch. This tunnel is then dissected from the pisiform to the thumb incision.

TECH FIG 4 • A. Release of EIP tendon for passage and radial dissection to locate and retrieve EIP tendon for transfer. **B.** Creation of a subcutaneous tunnel from the radial pisiform incision to the longitudinal thumb incision. **C.** EIP suture to APB tendon with braided permanent suture.

- The EIP tendon is passed from dorsal to volar, around the pisiform, and then to the thumb incision. It is sutured to the APB tendon and extensor hood with braided permanent suture (**TECH FIG 4C**).

Reconstruction of Index and Long Finger Flexion: Flexor Digitorum Profundus Side-to-Side Transfer

- A longitudinal incision is made over the distal third of the forearm.
- The flexor digitorum profundus (FDP) tendons are identified, deep to the median nerve (**TECH FIG 5A**).
- The FDP tendons are synchronized to recreate the digital cascade, and one

sutures the index through small finger tendons with two rows of braided permanent sutures (**TECH FIG 5B**).

Reconstruction of Thumb Flexion: Brachioradialis to Flexor Pollicis Longus

- A longitudinal incision is made along the distal third of the forearm. The same incision for the FDP transfer can be used (**TECH FIG 6A**).
- The brachioradialis (BR) is released from the radial styloid insertion and mobilized proximally to maximize the excursion (**TECH FIG 6B**).
- The FPL tendon is located under the flexor carpi radialis, in the deep volar compartment.
- The BR is weaved into the flexor pollicis longus (FPL) with multiple passes, after optimizing tension (**TECH FIG 6C,D**). Wrist extension should result in maximal thumb IP joint flexion and lateral pinch.

TECH FIG 5 • A. The FDP tendons are localized beneath the median nerve in the distal forearm. **B.** Tension is set between the radial two tendons (median innervated) and ulnar two tendons (ulnar innervated), recreating the digital cascade.

TECH FIG 6 • **A.** Design of incisions for high median nerve tendon transfers. **B.** Exposure of BR along insertion onto radial styloid. **C.** Tension is set between the BR and FPL. **D.** Final position of thumb after transfer, judging tenodesis with wrist flexion and extension.

PEARLS AND PITFALLS

Preoperative evaluation

- Critically assess donor muscle availability and strength.
- Determine patient goals and potential for additional nerve recovery.
- Release any areas of nerve compression for pain control, even if motor recovery is unlikely.

Thumb opposition

- Thumb should be in full opposition and IP joint flexed with wrist extension and should relax with wrist flexion.
- Ensure that subcutaneous tunnel is of ample size to allow easy tendon gliding.

Finger flexion

- Improvement in finger flexion may not improve grip strength given no additional motor units.

POSTOPERATIVE CARE

- Patient is usually splinted with the thumb in full opposition and wrist in flexion immediately after surgery. The fingers are free to move to maintain motion.
- At the first postoperative visit, an orthoplast splint is fabricated to maintain thumb opposition and slight wrist flexion. At 3 weeks, gentle active range of motion is commenced several times a day. Passive range of motion is started at 6 weeks. Strengthening is started at 8 weeks.
- A knowledgeable hand therapist plays an important role in the surgical outcomes.
- Early active range of motion for opposition transfers has been advocated by some surgeons, with quicker recovery and no evidence of pullout of the transferred tendon.⁴

OUTCOMES

- Most median nerve palsy patients can perform normal activities of daily living with their hand after complete recovery from surgery. The tendon transfers combine proper direction of action, pulley location, and force for success.⁵
- Extensor indicis proprius (EIP) opponensplasty is generally efficacious, with 88% of patients with excellent results—ie, 75% function of the opposite, normal thumb.⁶ It works best in the setting of supple hands.⁷ EIP is not synergistic with thumb opposition, so retraining can be more difficult than FDS transfers.

COMPLICATIONS

- Suboptimal results may be a result of choosing a weak motor for transfer or incorrect vector of pull.
- Tendon adhesions can result from prolonged immobilization, particularly if using a pulley to reroute the force of the muscle.
- Tendon ruptures can be prevented with patient education and progressive therapy advancement.

32 Tendon Transfers for Ulnar Nerve Injury

CHAPTER

Rafael J. Diaz-Garcia and Kevin C. Chung

DEFINITION

- Ulnar nerve palsy refers to the loss of motor control and sensation in the distribution of the ulnar nerve.
- Low ulnar nerve palsy refers to isolated loss of intrinsic hand function, whereas high ulnar nerve palsy refers to the additional loss of half the flexor digitorum profundus (FDP) and flexor carpi ulnaris (FCU).

ANATOMY

- The ulnar nerve is a mixed nerve composed of fibers from the C8 and T1 roots via the medial cord of the brachial plexus.
- It lies posteromedial to the brachial artery in the upper arm, prior to piercing the intramuscular septum 8 to 10 cm proximal to the medial epicondyle. It has no branches in the arm.
- It passes through the cubital tunnel into the forearm, running between FCU and FDP, innervating the former and 0.5 of the latter.
- Approximately 6 to 7 cm proximal to the ulnar styloid, the dorsal sensory branch leaves the main nerve to innervate the dorsoulnar hand and dorsal proximal phalanges of the small and ring fingers.
- The ulnar nerve continues into the hand through the Guyon canal at the wrist, splitting into a superficial sensory branch and a deep motor branch. The sensory branch supplies innervation to the small finger and ulnar half of the ring finger. The motor branch supplies the hypothenar muscles, ulnar lumbricals, interossei, adductor pollicis, and the deep head of flexor pollicis brevis.
- Martin-Gruber and Riche-Cannieu connections represent anomalous

innervation patterns between the median and ulnar nerves, which may complicate the findings on exam.

PATHOGENESIS

- The pathogenesis of ulnar nerve palsy is most frequently secondary to trauma. Injury may come in the form of a laceration along its course, an axonotmetic injury, or an avulsion of the roots. Proximal injuries that involve the medial cord may also have sensory disturbances in the arm or forearm due to involvement of the medial brachial and antebrachial cutaneous branches.
- Systemic conditions such as Charcot-Marie-Tooth disease, leprosy, and syringomyelia can cause ulnar neuropathy as well.¹ Systemic conditions are unlikely to present with isolated ulnar nerve symptoms.

NATURAL HISTORY

- With prolonged ulnar nerve palsy, secondary deformities of the hand will develop with attenuation of the central slips and flexion contractures of the interphalangeal joints.
- The disability and deformity is directly related to the degree of the nerve injury. If tendon transfers are being considered, nerve recovery is unlikely.

PATIENT HISTORY AND PHYSICAL FINDINGS

- It is important to identify the cause and timing of ulnar nerve palsy to determine if the pathology can be reversed. Acute repair of lacerated nerves, nerve transfers, and decompressions should be done sooner rather than later to prevent irreversible loss of the motor end plates in the innervated muscles.
- Tendon transfers are indicated when no further recovery of the nerve or the ulnarly innervated muscles is expected.
- Working from distal to proximal, testing muscle and sensory function can help localize the level of the lesion. The first dorsal interosseous is the last muscle innervated by the ulnar nerve. Involvement of only motor function implies a lesion in the deep motor branch, distal to the Guyon canal. Loss of sensation along the dorsoulnar aspect of the hand implies a lesion proximal to the takeoff of the dorsal sensory branch. Loss of distal interphalangeal (DIP) flexion of the ring and small fingers implies high ulnar nerve palsy, due to involvement of the FDP. Loss of sensation along the medial arm or forearm implies a lesion in the brachial plexus.
- There are many eponymous physical findings found in ulnar nerve palsy, most

of which are functional losses of intrinsic hand muscles:^{2,3}

- Froment sign: hyperflexion of the IP joint of the thumb when attempting forceful adduction, due to substitution of flexor pollicis longus (FPL) for adductor pollicis
- Jeanne sign: hyperextension of the metacarpophalangeal (MCP) joint of the thumb as a reciprocal result of over use of FPL
- Wartenburg sign: abduction of small finger due to paralysis of intrinsics with unimpeded abduction by extensor digiti minimi
- Duchenne sign: hyperextension of the MCP joints and flexion of the PIP joints, secondary to paralysis of ulnarly innervated interosseous and lumbricals
- Masse sign: flattening of the metacarpal arch
- Pollack sign: loss of DIP flexion of the ring and small fingers in high ulnar nerve palsy
- The Bouvier maneuver is a preoperative test to assess IP joint extension if MCP hyperextension is blocked. In theory, a positive Bouvier—that is to say, intact IP extension with MCPs held in flexion—implies that addressing MCP hyperextension with a static procedure should correct claw deformity. In reality, static soft tissue procedures tend to stretch out and most patients would do best with a dynamic tendon transfer.⁴

IMAGING

- Initial workup for an ulnar nerve lesion usually warrants nerve conduction studies and electromyography to determine location and extent of injury.
- MRI of the brachial plexus may be warranted if there is concern for a lesion at this level.

DIFFERENTIAL DIAGNOSIS

- Isolated ulnar nerve compression
- Isolated ulnar nerve injury
- Traumatic lower plexopathy
- Cervical radiculopathy
- Leprosy
- Syringomyelia

NONOPERATIVE MANAGEMENT

- An occupational therapist can be helpful in the nonoperative management of

ulnar nerve palsy.

- An anticlaw splint (dorsal blocking at the MCP joint with IP joints free) can be used to preserve extensor integrity while the nerve recovers or as a long-term functional orthosis.
- Flexion contractures must be prevented or treated prior to tendon transfers, as maximum passive motion must be acquired before any tendon transfers.
- Fixed flexion contractures should be addressed with serial casting, if needed.

SURGICAL MANAGEMENT

- There are three key functions that tendon transfers must address in the setting of ulnar nerve palsy:
 - Thumb adduction to recreate key pinch
 - Improved grip by addressing claw deformity and MCP hyperextension
 - Flexion of ring and small finger DIP joints, in those with a high ulnar palsy
- Unlike nerve transfers, tendon transfers do not have a firm time period in which they must be performed. Tendon transfers can be delayed while awaiting potential nerve recovery.
- The common principles of tendon transfers are as follows:
 - Joint contractures should be addressed prior to any transfers.
 - Each muscle transfer should address one specific function.
 - Transferred tendons should glide through a smooth and scar-free surgical site.
- Thumb adduction can be addressed with either extensor carpi radialis brevis (ECRB) or flexor digitorum superficialis (FDS), with the former being our preference. Transfers for adduction require a pulley distal to the pisiform for the transfer to be effective.
- Claw deformity of the fingers can be addressed with either static or dynamic procedures. For static procedures to be indicated, the Bouvier maneuver must be positive. Static procedures prevent hyperextension of the MCP joint but often stretch out over time unless the joint undergoes arthrodesis.⁵ Dynamic procedures use FDS, ECRB, extensor carpi radialis longus, or flexor carpi radialis. The FDS transfers are preferable because they do not require tendon grafts, which may be prone to adhesion. High ulnar nerve palsy precludes use of the FDS tendons in the ring and small finger for transfers.

Preoperative Planning

- Tendon transfers should be delayed until after potential nerve recovery is

completed.

- Clinical exam of the patient will allow the surgeon to decide what functions must be recreated and what donor muscles are available for each function.

Positioning

- The patient is placed in the supine position with a tourniquet on the upper arm.
- The OR lights are positioned with one projecting from proximally and one distally from the operative site.

Approach

- Like with all tendon transfers, one should plan for the tendons to glide through a smooth and scar-free wound bed and each transfer should be for one function.
- To recreate the intrinsic function of the hand, the transferred tendons should pass volar to the axis of the MCP joint prior to inserting on the dorsal extensor apparatus.

TECHNIQUES

■ Claw Deformity of Digits

Metacarpal Capsulodesis^{6,7}

- Indicated only with a positive Bouvier maneuver
- An incision is made in line with the distal palmar crease, over the A1 pulley of the ring and small fingers.
- The A1 pulley is exposed and released longitudinally, protecting the neurovascular bundles and exposing the volar plate of the MCP joint (**TECH FIG 1**).
- A distally based, rectangular-shaped flap of volar plate is created by releasing the proximal attachment off the metacarpal.
- A 30-degree flexion contracture is created with the volar plate advanced proximally, and bone anchors are used to maintain position of the joint.
- As noted before, this procedure can be technically difficult to perform because the exposure is limited and the volar plate cannot be advanced easily. This type of soft tissue reconstruction does stretch out rather quickly. A truly predictable static procedure is MCP joint fusion.

Flexor Digitorum Superficialis Lasso

- An incision is made in line with the distal palmar crease, over the A1 pulleys of the ring and small fingers.
- The A1 and A2 pulleys are exposed, preserving the neurovascular bundles.
- The FDS insertion is preserved to reduce the likelihood of a swan-neck deformity. The FDS is released at A2 pulley and sutured back to itself proximal to the A1 pulley, creating a tendinous loop (**TECH FIG 2A**).
- Set the tension with the MCP joint at 40 to 50 degrees of flexion with the wrist at neutral, recreating the usual digital cascade of the hand (**TECH FIG 2B**).
- The FDS middle finger can be split into four tails in a more proximal incision and similarly tensioned at each A1 pulley.

TECH FIG 1 • A1 pulley is released longitudinally and a rectangular-shaped flap of volar plate is created. Flexion contracture is created with the proximally advanced volar plate and bone anchors maintain position of the joint.

Stiles-Bunnell Transfer of FDS to Lateral Bands^{8,9}

- One FDS tendon can be used to power two digits or four digits. The ring and small finger FDS is not used in the setting of high ulnar nerve palsy to preserve flexion of the ring and little fingers when the FDP to these two fingers is paralyzed.
- A Bruner incision is made over the proximal phalanx between the A2 and A3 pulleys. A separate longitudinal incision is made over the proximal phalanx between the glabrous and nonglabrous skin to expose the radial lateral band (**TECH FIG 3A**).
- The FDS is divided just proximal to the insertion and split into four slips as proximally as possible (**TECH FIG 3B**).

TECH FIG 2 • A. FDS tendon is released at distal edge of A2 pulley via Bruner incision. **B.** FDS tendon is sutured back to itself to create a flexion contracture at MCP joint.

TECH FIG 3 • **A.** The FDS of the middle finger is released from the insertion on middle phalanx. **B.** Four tails are created for transfer to the digits. **C.** FDS is transferred to the lateral bands of each digit, radial of the middle-small and ulnar of the index. **D.** Final position after transfer shows MCP flexion composite with FDS pull.

- FDS slip is passed through lumbrical canal, deep to the neurovascular bundle, with a tendon passer or hemostat to the radial aspect of the middle through small fingers and the ulnar aspect of the index. It is key to stay palmar to the deep metacarpal ligament to maintain the force palmar to the axis of rotation (**TECH FIG 3C**).
- FDS slips are attached to the lateral band with the wrist at neutral, trying to recreate the digital cascade. MCP flexion should be at 50 to 70 degrees and IP joints in full extension (**TECH FIG 3D**).
- Passive wrist flexion should result in full MCP extension.

ECRB to Lateral Bands With Tendon Graft^{9,10}

- ERCB is used when the FDS is not available, for example, high median and ulnar nerve palsy when the reinnervated median nerve muscles are too weak to transfer.
- A small transverse incision is made over the third metacarpal base, through which the ECRB is transected at its insertion.
- The ECRB tendon is retrieved proximal to the retinaculum through a separate incision.
- Incisions are made at the metacarpal necks in the second/third metacarpal interval and fourth/fifth metacarpal interval.
 - Excising a small window of paralyzed interosseous muscle creates a path for each tendon graft.
- Longitudinal incisions are made over the proximal phalanges of the index through small fingers, exposing the lateral bands.
- A tendon graft is passed volarly to the intermetacarpal ligament and through the intermetacarpal windows.
- The tendon grafts are sutured to the radial lateral bands of the middle through small fingers and the ulnar lateral band of the index.
- The grafts are sewn to each other and then to the ECRB (**TECH FIG 4**).
 - Tension should be done with the wrist in full extension and the fingers in an intrinsic-plus position.
 - MCP extension should happen with wrist flexion.

TECH FIG 4 • A. Tendon graft is passed volarly to the intermetacarpal ligament and through the intermetacarpal windows. **B.** Tendon grafts are

sutured to the radial lateral band of the middle finger and the ulnar lateral band of the index finger. Tendon transfer is sutured into the lateral band.

■ Restoration of Thumb Adduction: ECRB to Adductor Pollicis With Tendon Graft

- A small transverse incision is made over the third metacarpal base, through which the ECRB is transected at its insertion.
- The ECRB tendon is retrieved proximal to the retinaculum through a separate incision.
- A path for the tendon graft is created between the third and second metacarpals, incising skin and excising a small window of paralyzed interosseous muscle.
- A longitudinal incision is made along the ulnar aspect of the thumb MCP joint, exposing the adductor aponeurosis.
- A tendon graft (often palmaris) is passed deep to the adductor pollicis and through the window between the metacarpals (**TECH FIG 5**).
- The graft is tensioned so that the thumb is adducted past the index metacarpal when the wrist is at neutral. In dorsiflexion, the thumb is abducted, and in palmar flexion, it should lie firmly against the palm.

TECH FIG 5 • A. A transverse incision is made over the third metacarpal base and the ECRB is transected at insertion. The ECRB tendon is retrieved proximal to the retinaculum through another incision. **B.** The

palmaris longus tendon graft is passed to the adductor pollicis.

■ Thumb Stabilization: Split Flexor Pollicis Longus (FPL) to Extensor Pollicis Longus (EPL) Tenodesis

- The muscle imbalances of the ulnar paralyzed hand, particularly due to the loss of the adductor pollicis, result in greater flexion of the IP joint and less of the MCP. This creates a Z-deformity in about 60% of patients.¹¹
- A radial incision is made over the proximal phalanx of the thumb.
- Preserving the oblique pulley, the FPL and EPL are exposed.
- The radial half of the FPL is released from the distal insertion and weaved into the EPL (**TECH FIG 6**).
- The interphalangeal joint is kept in extension with a 0.045-in. K-wire.

TECH FIG 6 • **A.** The radial half of the FPL is released from the rest of the tendon at the insertion site. **B.** This radial slip is transferred dorsally. **C.** Final position after transfer shows IP joint stabilization.

■ Restoration of Finger Flexion: Flexor Digitorum Profundus (FDP) Side-to-Side Transfer

- High ulnar nerve palsy results in paralysis of the ulnar 0.5 of FDP, affecting motion of the DIP joints of the ring and small fingers and thus grip strength.
- Side-to-side transfer is an easy way to address this with the median nerve innervated portion of the muscle.
- A longitudinal incision is made over the distal third of the forearm.
- The FDP tendons are identified, deep to the median nerve.
- The FDP tendons are synchronized to recreate the digital cascade, and one sutures the long through small finger tendons with two rows of braided permanent sutures.

PEARLS AND PITFALLS

Preoperative evaluation

- Critically assess donor muscle availability and strength.
- Determine patient goals and potential for additional nerve recovery.
- Determine the integrity of the PIP central slip with the Bouvier maneuver.

Thumb adduction

- The thumb may have joint instability that requires additional procedures such as capsulodesis or arthrodesis.

Addressing claw deformity

- Static transfers usually stretch over time and should be reserved for combined nerve injuries.
- Transfers must pass volar to the MCP joint to address hyperextension.
- Dynamic transfers should be sewn into lateral bands if Bouvier maneuver is negative.

POSTOPERATIVE CARE

- The patient is usually splinted with the MCP joints in 60 to 70 degrees of flexion and the IP joints in full extension (intrinsic plus position) for a total of 4 weeks. Active range of motion exercises are then commenced, with a dorsal blocking splint at the MCP joint.

- Passive range of motion is started at 6 weeks. Strengthening is started at 8 weeks for the adductor plasty and 10 weeks for the intrinsic transfers.
- A knowledgeable hand therapist plays an important role in the surgical outcomes.
- Early active range of motion has been advocated by some surgeons, with quicker recovery and less pain.^{12,13}

OUTCOMES

- Outcome studies are difficult to compare due to the heterogeneity of the patient populations.
- Static reconstructions often stretch. Less than 50% of the hands treated with capsulodesis see long-term improvement in regard to clawing.¹⁴
- Wrist extensor transfers to the lateral bands restore grip strength most effectively, with the highest efficacy in those with short-standing paralysis.¹⁵ However, the need for tendon grafts and scarring through the interosseous muscles makes them less favorable.^{16,17}
- FDS transfers are most efficacious in addressing claw deformity, with minimal improvement in grip strength.^{15,18}

COMPLICATIONS

- Complications are more common with the intrinsic transfers due to the delicate balance in the extensor mechanism.
- Transfers may be ineffective due to poor tensioning and may need surgical revision to tighten the insertion.
- Transfers that are too tight can often be addressed with passive range of motion exercises to stretch the transfer.
- Harvest of FDS results in a swan-neck deformity fairly commonly, with the incidence ranging from 15% to 85%.^{15,19,20}

33 Tendon Transfers for Radial Nerve Injury

CHAPTER

Rafael J. Diaz-Garcia and Kevin C. Chung

DEFINITION

- Radial nerve palsy refers to the loss of motor control and sensation of the hand in the distribution of the radial nerve.
- Loss of extensor function of the wrist and digits is the greatest deficit, as the sensation loss is of little consequence in prehension because it is on the dorsum of the hand. Loss of wrist extension affects grip strength.

ANATOMY

- The radial nerve is a mixed nerve composed of fibers from the C5 through T1 roots, forming as a terminal branch of the posterior cord of the brachial plexus.
- It travels initially in the posterior compartment of the arm, where it gives off multiple branches to the three heads of the triceps while coursing along the spiral groove of the humerus. It passes through the intermuscular septum into the anterior compartment, where it lies between the brachialis and brachioradialis (BR), innervating the latter.
- The BR, extensor carpi radialis longus (ECRL) and, at times, extensor carpi radialis brevis (ECRB) are innervated by the proper radial nerve prior to its entering the supinator, where it then divides into its two terminal branches.
- The superficial branch of the radial nerve provides sensation to the radial dorsum of the hand and fingers except for the small finger and ½ of the ring finger.
- The deep branch of the radial nerve innervates the supinator and becomes the posterior interosseous nerve (PIN) as it exits, innervating ECRB, extensor digitorum communis (EDC), extensor carpi ulnaris (ECU), abductor pollicis longus (APL), extensor pollicis brevis (EPB), extensor pollicis longus (EPL),

and extensor indicis proprius (EIP).

- Order of innervation is consistent, with EPL and EIP as the last two innervated muscles. This is helpful with clinical examination at time of injury and monitoring recovery.

PATHOGENESIS

- The pathogenesis of radial nerve palsy is most frequently due to traumatic injury, which can happen from injuries extending from the brachial plexus to the forearm.
- Idiopathic and compression causes are rarely seen.
- Radial nerve injury is most commonly seen with humeral shaft fractures, given its location in the spiral groove.¹⁻³

NATURAL HISTORY

- The mechanism of injury is an important predictor of potential recovery.
- Open, high-energy, and penetrating injuries should be explored early, as they have demonstrated poor recovery with nonoperative management.⁴

PATIENT HISTORY AND PHYSICAL FINDINGS

- A patient with radial nerve injury will present with potential loss of elbow extension, wrist extension, digital extension, thumb extension, and thumb abduction.
- The BR and ECRL are preserved in PIN palsies, as they are innervated proximal to the elbow.
- Tenodesis on physical exam can differentiate extensor tendon injury vs nerve palsy.

IMAGING

- Initial workup for acute radial nerve palsy may warrant x-rays to determine if there are any fractures or dislocations in the extremity associated with the acute trauma.
- Nerve conduction studies and electromyography may be helpful in the workup of radial nerve palsy, helping to determine the level of the lesion. Axonal loss is evident 3 weeks after injury.
- MRI of the brachial plexus may be warranted if there is concern for a lesion at this level.

DIFFERENTIAL DIAGNOSIS

- Extensor tendon laceration/rupture
- Isolated radial nerve injury
- Cervical radiculopathy
- Volar subluxation of the MCP joint (in inflammatory arthritis)
- Brachial plexus lesion

NONOPERATIVE MANAGEMENT

- Hand therapy is essential to educate the patient in a home exercise program to maintain motion and prevent contracture while waiting for nerve recovery.⁵
- Patients should be given a wrist splint for support to counteract the unopposed wrist flexors. Hand intrinsic muscles can provide some digital extension.

SURGICAL MANAGEMENT

- The goals of reconstruction depend on the level of injury of the radial nerve.
 - Injuries in the arm require reconstruction of independent wrist extension, finger extension, and thumb extension.
 - Injuries in the forearm of the PIN will spare the ECRL and sometimes the ECRB, which preserve wrist extension.
- Donor muscles include the pronator teres (PT), flexor carpi ulnaris (FCU), flexor carpi radialis (FCR), flexor digitorum superficialis (FDS), and palmaris longus (PL). The different reconstructions are usually referred to by which transfer is used for reconstruction of digital extension.
- Tendon transfers should be delayed until after potential nerve recovery is completed. However, unlike median or ulnar nerve transfers, sometimes radial nerve transfers are done at the time of nerve repair/reconstruction to minimize need for bracing.

Preoperative Planning

- Clinical exam of the patient helps the surgeon decide what functions must be recreated and what donor muscles are available for each function.
- Hand and wrist joints should be as supple as possible.
 - Wrist motion, particularly flexion, is an important characteristic for radial nerve transfers. That is because additional excursion is obtained with wrist flexion to help the FCR or FCU to fully extend the fingers.
 - If there is significant wrist stiffness, one should consider FDS to EDC transfers for better excursion of the transfer.

Positioning

- The patient is placed in the supine position with a tourniquet on the upper arm.
- The OR lights are positioned with one projecting from proximally and one distally from the operative site.

Approach

- Like with all tendon transfers, one should plan for the tendons to glide through a smooth and scar-free wound bed and each transfer should serve one function.
- If there is scarred tissue along the path of the transfer, it must be replaced by soft supple tissue either through serial scar excision or a flap procedure.

TECHNIQUES

■ Reconstruction of Wrist Extension: Pronator Teres to Extensor Carpi Radialis Brevis

- A radial-sided longitudinal incision is planned over the midpoint of the forearm to expose both the PT and the second extensor compartment (**TECH FIG 1A,B**).
- The pronator teres (PT) is identified inserting on the radial shaft, deep to the brachioradialis (BR) and radial artery.
 - Additional length is acquired by harvesting a strip of distal periosteum along with the distal tendon.
- The proximal PT is freed of its attachments to the other volar muscles to improve the excursion.
- The extensor carpi radialis brevis (ECRB) is localized just distal to the musculotendinous junction. A smooth path is created over the BR and the superficial radial nerve.
- The PT is passed over the BR to the ECRB. The ECRL can also be incorporated into the tendon transfer, but this is typically not done.
- If the ECRL and ECRB has no chance of recovery, the tendon transfer is done in the end-to-end fashion, rather than end-to-side to provide maximum excursion. Tension is set.
- A Pulvertaft tendon weave is done using 2-0 braided nonabsorbable sutures.
- The wrist tendons are reconstructed first to facilitate setting tension for the

fingers and thumb.

- The wrist should be at a neutral posture after the tendon transfer is secured.
- Each end of the tendon is grasped with a clamp to set the tension, and if the tension is too loose, horizontal mattress sutures are used to “fine-tune” and tighten the transfer (**TECH FIG 1C–E**).

TECH FIG 1 • A,B. The PT is identified where it inserts on the radial shaft, deep to the brachioradialis. **C,D.** The PT is woven through ECRL and ECRB tendons just distal to the musculotendinous junction. **E,F.** Path of the transfer.

■ Reconstruction of Finger Extension

Flexor Carpi Radialis to Extensor Digitorum Communis^{6,7}

- A longitudinal volar incision is used to expose the flexor carpi radialis (FCR) and palmaris longus in the distal forearm.
 - The distal tendon is transected at the distal wrist crease.
- There are two paths of transfer of the FCR.
 - A subcutaneous tunnel in a radial direction to the dorsum of the wrist. This is our preferred transfer, as the path is created for the EPL as well.
 - A tunnel through the interosseous membrane (IOM) to the dorsum of the wrist. This has a more direct line of pull but has a higher incidence of postoperative adhesions.
- Point of insertion on each tendon is chosen to recreate the normal digital cascade by detaching each finger tendon and suture it along the path of the FCR.
- Pulvertaft weaves are held in place with nonabsorbable sutures (**TECH FIG 2A–C**).
- Final tension is set to achieve the tenodesis posture: 30-degree wrist extension is accompanied by 90 degrees of finger flexion; 30 degrees of wrist flexion is accompanied by full finger extension (**TECH FIG 2D,E**).

Flexor Carpi Ulnaris to Extensor Digitorum Communis^{8–10}

- A longitudinal incision is made over the distal aspect of the flexor carpi ulnaris (FCU) tendon at the pisiform.
 - The ulnar neurovascular bundle must be identified and protected.
- The FCU is freed from its surrounding attachments to achieve sufficient excursion.
- A broad subcutaneous tunnel is created in an ulnar direction toward the dorsum of the wrist.
- A dorsal incision is made to expose the extensor digitorum communis (EDC) and release the proximal extensor retinaculum.
- Pulvertaft weaves are held in place with nonabsorbable sutures (**TECH FIG 3**).
- Point of insertion and tensioning is done similarly to the FCR transfer.

TECH FIG 2 • A. The FCR to EDC is completed via a subcutaneous tunnel along the radial side of the wrist. **B,C.** Relationship between the FCR donor and the EDC tendons. The transfer can be either subcutaneous or transinterosseous membrane. **D.** Full digital extension is seen with slight wrist flexion. **E.** Full digital flexion is possible with wrist extension.

TECH FIG 3 • The FCU to EDC is completed via a

subcutaneous tunnel along the ulnar side of the wrist. Care is kept to ensure there is no injury or compression to the dorsal ulnar sensory branch. The distal FCU muscle can be debrided if it makes the weave too bulky.

Flexor Digitorum Superficialis (FDS-IV) to Extensor Digitorum Communis¹¹

- FDS to EDC transfer is best suited for patients with poor wrist motion preoperatively.
 - The better excursion of the FDS (70 mm) results in better digital extension.
 - In most patients, wrist motion from tenodesis compensates for the limited excursion of the wrist flexors.
- The FDS tendon is released from the ring finger just proximal to the carpal tunnel via a volar wrist incision.
 - Alternatively, it can be released at the PIP joint through a Bruner-style incision if greater tendon length is needed in the case of tendon rupture or loss.
- For radial nerve palsy, when the extensor tendons are intact, the FDS is transected at the wrist and will be transferred dorsally to attach to the extensor tendons proximal to the extensor retinaculum.
- It is retrieved from the volar forearm incision used to harvest the other tendons.
- The FDS to the long finger is transferred to the index and thumb extensor tendons, coordinating both these digits for precise pinch (**TECH FIG 4A–C**).
- The IOM is exposed proximal to the pronator quadratus.
- Making sure to not disrupt the central band of the IOM, an opening is made to allow for the tendons to pass from volar to dorsal (**TECH FIG 4D**).
- Dorsally, the FDS-IV is transferred to the EDC long through small fingers with a Pulvertaft weave.
- This transfer is grouped in this fashion to coordinate the ulnar digits in power grip.
- Tension is set with the wrist at 30 degrees of extension and the MP joints at full extension (**TECH FIG 4E**).

TECH FIG 4 • **A,B.** Dorsal and volar incisions, respectively, are designed for exposure of tendons. **C.** The FDS to the long and ring fingers are divided just proximal to the carpal tunnel. **D.** The tendons are passed from volar to dorsal via the interosseous membrane. **E.** The FDS-IV is woven into the EDC tendons (*yellow arrow*), and the FDS-III is woven into the EPL and EIP (*black arrow*).

■ Reconstruction of Thumb Extension: Palmaris Longus to Extensor Pollicis Longus

- Palmaris longus (PL) is identified through the volar incision used to expose FCR. It is freed from its surrounding attachments to maximize excursion.
- A subcutaneous tunnel toward the thumb is created below the radial artery

and cutaneous nerves along the radial aspect of the wrist (**TECH FIG 5A**).

- If nerve recovery is not expected, the extensor pollicis longus (EPL) tendon is released proximally through the dorsal incision.
- If nerve recovery is expected and transfer is being used as a temporizing measure, the EPL is kept in continuity but released from the third compartment to improve the vector of pull of the transfer.
- A Pulvertaft weave is done between the PL and EPL tendons.
- Tension is set with the thumb fully extended with the wrist in neutral.
- Transfer is secured with nonabsorbable suture (**TECH FIG 5B–D**).

TECH FIG 5 • A. FCR and PL can both be harvested from the same radial incision. **B.** FCR is woven to EDC and PL is woven to EPL. **C,D.** Transfer of PL to EPL.

PEARLS AND PITFALLS

Preoperative evaluation

- Critically assess donor muscle availability and strength.
- Determine patient goals and potential for additional nerve recovery. Tendon transfers for wrist extension and thumb extension may be

done even with expected recovery.

- Because wrist flexors do not match excursion of finger extensors, preoperative assessment can help determine working range of transfer and how to set tension.¹²

Finger extension transfer

- Choice between FCR and FCU for digital extension is not straightforward. Neither matches excursion, though FCU has greater force. However, loss of FCU may result in loss of “dart thrower’s motion.”
- Interosseous membrane passage must allow for easy tendon gliding. Prone to greater adhesions.

POSTOPERATIVE CARE

- The patient is usually splinted with the wrist in 30 to 40 degrees of extension and the MP joints in full extension. The interphalangeal joints can undergo passive range of motion, as the intrinsic hand muscles drive their extension.
- At the first postoperative visit, an Orthoplast splint is fabricated to wrist and MP extension. At 3 weeks, gentle active range of motion of the wrist is commenced several times a day. Integration of digital extension is added as wrist motion improves. Passive range of motion is started at 6 weeks. Strengthening is started at 8 weeks.
- A knowledgeable hand therapist plays an important role in the surgical outcomes.

OUTCOMES

- Most radial nerve palsy patients can perform normal activities of daily living with their hand after complete recovery from surgery.
- With restoration of wrist extension, grip strength is 40% to 50% of the contralateral side and digital extension is 34% to 75% of normal.^{12–14}

COMPLICATIONS

- Suboptimal results may be a result of choosing a weak motor for transfer or incorrect vector of pull.
- Radial deviation can result from use of FCR. PIP joint hyperextension or flexion contractures can result from use of FDS tendons.
- Tendon adhesions can result from prolonged immobilization, but tenolysis should not be considered until at least 9 months out from surgery.
- Tendon ruptures can be prevented with patient education and progressive

therapy advancement. Transfer attenuation may require revision.

34 Tendon Transfers for Combined Median and Ulnar Nerve Injury

CHAPTER

Kate Elzinga and Kevin C. Chung

DEFINITION

- Combined median and ulnar nerve injuries cause major impairment of the upper extremity. The ability to perform fine pinch and power grasp is lost. The volar and dorsoulnar hand is insensate. The balance between the flexor and extensor muscle groups of the upper extremity is absent. Prehensile function is greatly reduced.
- Low median and ulnar nerve injuries are the most common combined nerve injury of the upper extremity. Nerve lacerations should be repaired acutely. In the case of a delayed nerve injury presentation or incomplete recovery following nerve repair, tendon transfers can be used to augment function.
- Tendon transfers can be combined with nerve transfers and free muscle transfers to help maximize the function of the injured upper limb. However, in combined nerve injuries, the number of nerves available for transfer is also limited.
- For a successful tendon transfer, a redundant tendon is harvested for transfer, minimizing donor-site morbidity while restoring a lost function. Finding an appropriate donor tendon is more difficult in combined nerve injuries compared to isolated nerve injuries; a greater number of tendons are affected, which results in multiple functional deficits while fewer intact tendons remain for transfer.
- Sensory deficits are also greater in combined nerve injuries (**FIG 1**). Reconstructive outcomes are inferior in combined nerve injuries compared to single nerve injury injuries.
- Donor-site morbidity must be carefully considered prior to tendon harvest for

transfer in combined nerve injuries. These patients have a limited number of tendons available for transfer. The patient's individualized goals must be carefully considered. A personalized reconstructive plan is created to best restore the patient's function.

- The patient's physical exam is central in formulating the operative plan. Missing functions, as well as available donor tendons, are documented. Once the functional deficits and available donors have been determined, the donors are matched to the deficits for reconstruction.
- Following the principles of tendon transfers optimizes patient outcomes:
 - Expendable donor
 - Straight line of pull
 - One muscle for one function
 - Similar force of contraction
 - Adequate excursion
 - Synergism
 - Skeletal stability
 - Stable, supple soft tissue bed
 - Full passive range of motion (ROM)
- Synergistic transfers are the most intuitive for patients to learn and offer the quickest return of function. Wrist extension is synergistic with finger flexion, whereas wrist flexion is linked with finger extension.
 - Compared to single nerve injuries, following a combined nerve injury, achieving synergy can be more difficult.
- Ideally, tendon excursion of the donor tendon should match that of the recipient tendon to best restore the biomechanics of the upper extremity. The wrist flexors and extensors have 3.3 cm of excursion, the finger extensors have 5 cm of excursion, and the finger flexors have 7 cm of excursion.¹
- Staging of procedures is important. Only tendon transfers that can be rehabilitated with hand therapy together should be performed at the same time. Multiple surgeries may be required.

ANATOMY

- Proximally, the median nerve innervates the pronator teres, flexor carpi radialis (FCR), palmaris longus (PL), and flexor digitorum superficialis (FDS).
- The anterior interosseous nerve (AIN) originates from the median nerve 6 to 8 cm distal to the medial epicondyle. It innervates the flexor digitorum profundus (FDP) to the index and middle fingers, flexor pollicis longus (FPL), and

pronator quadratus.

- The median nerve continues distally to provide motor innervation to the lumbricals to the index and middle fingers and the thenar muscles (abductor pollicis brevis [APB], flexor pollicis brevis [FPB], and opponens pollicis) and sensory innervation to the thumb, index, middle, and radial half of the ring finger.
- A low median nerve injury, distal to the origin of the AIN, causes the loss of thumb opposition and sensory deficits in the volar-radial hand.
- A high median nerve injury affects all of the muscles listed above. In addition to thumb opposition and sensory deficits, forearm pronation is lost, wrist flexion is weakened, flexion of all four proximal interphalangeal (PIP) joints as well as the index and middle finger distal interphalangeal (DIP) joints is lost, and thumb flexion is lost.
- The ulnar nerve innervates, from proximal to distal, the flexor carpi ulnaris (FCU), FDP to the ring and small fingers, hypothenar muscles (abductor digit minimi [ADM], opponens digiti minimi, flexor digiti minimi), lumbricals of the ring and small fingers, dorsal and palmar interossei, deep head of the FPB, and adductor pollicis (AdP). The ulnar nerve provides sensory innervation to the ulnar ring and bilateral small fingers.

FIG 1 • Following a combined median and ulnar nerve injury, sensory deficits are profound in the hand. All volar hand sensation is lost. Dorsal sensation over the index and middle fingers distal to the PIP joints and

over the entire ring and small fingers is also absent.
Yellow, median nerve; *blue*, ulnar nerve; *pink*, radial nerve.

- A low ulnar nerve injury denervates the intrinsic muscles (hypothenar muscles, lumbricals ring and small fingers, interossei, deep head of FPB, AdP) of the hand.
- A high ulnar nerve injury occurs more proximally and denervates the extrinsic muscles (FCU, FDP ring and small fingers) of the hand in addition to the intrinsic muscles.
- Connections are common between the ulnar and median nerves, occurring in 9% to 27% of forearms^{1,2} and 83% of hands.³ However, connections between the radial nerve to either the median or the ulnar nerve have not been reported. In combined median and ulnar nerve injuries, motor and sensory deficits are profound and complete.
- A combined low median and ulnar nerve injury leads to the loss of thumb opposition and hand intrinsic function (thenar and hypothenar muscles, lumbricals, interossei). Forearm pronation, wrist flexion, and finger flexion are preserved. Hand sensation remains intact in the distribution of the superficial branch of the radial nerve over the dorsoradial hand only.
- In addition to the deficits of a low combined palsy, a combined high median and ulnar nerve injury results in the loss of forearm pronation, wrist flexion, finger flexion, and thumb flexion.
- The radial nerve innervates, from proximal to distal, the triceps, brachioradialis (BR), extensor carpi radialis longus (ECRL), extensor carpi radialis brevis (ECRB), supinator, extensor carpi ulnaris (ECU), extensor digitorum communis (EDC), extensor digit minimi (EDM), abductor pollicis longus (APL), extensor pollicis longus (EPL), extensor pollicis brevis (EPB), and the extensor indicis proprius (EIP).
- Expendable radial nerve-innervated tendons for wrist and hand reconstruction include:
 - The BR can be transferred if the biceps and/or brachialis are intact to maintain elbow flexion. The biceps and brachialis muscles are innervated by the musculocutaneous nerve and are not affected by median and ulnar nerve injuries.
 - Two of three of the ECRL, ECRB, and ECU can be harvested. One of these

tendons must be preserved to maintain wrist extension.

- The EIP and EDM can be transferred if the EDC is intact to maintain extension of the index and small fingers.
- The EPB can be harvested if the EPL is intact to provide thumb extension.
- The APL has multiple slips. As long as one slip of the APL is preserved for thumb abduction, the additional slips can be harvested for transfer.

PATHOGENESIS

- Lacerations to the volar wrist are the most common cause of combined low median and ulnar nerve injuries. The median and ulnar nerves are at increased risk in the distal volar forearm because of their superficial location here compared to their location deep to the muscles in the proximal forearm and arm.
- More proximal injuries, typically resulting from sharp mechanisms, can result in high combined nerve injuries.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Selection of appropriate donor tendons for transfer is critical to restore function while minimizing donor-site morbidity.
- A comprehensive history and physical examination is performed to determine the patient's functional deficits and their reconstructive goals.

FIG 2 • This patient had a low combined median and ulnar nerve injury of the right hand. A claw hand deformity is viewed from dorsal **(A)** and lateral **(B)**. The finger MCP joints are extended, and the IP joints are flexed.

- The patient's age, handedness, occupation, and avocations are documented.
- Limitations in activities of daily living, recreation, and work are discussed.
- The patient's goals are explored, including their plans for return to work, their availability and willingness to undergo secondary procedures and hand therapy, and the importance of appearance.
- Discussion with the patient's hand therapist provides further insight into the patient's deficits and can help prioritize reconstructive goals. Reconstruction is focused on providing the most functional benefit to each individual patient.
- The patient's compliance with therapy and their anticipated ability to retrain transferred tendons is assessed by the therapist and considered when determining the reconstructive plan.
- Important considerations from the patient's past medical history include smoking, diabetes mellitus, peripheral vascular disease, connective tissue disorders, arthritis, Dupuytren disease, and previous hand injuries.
- On physical examination, a claw hand deformity is more apparent in a low median and ulnar nerve palsy than in a high injury (**FIG 2**).
 - In low injuries, FDS and FDP innervation remain intact causing unopposed flexion of the interphalangeal (IP) joints of the fingers due to the denervation of the interossei and lumbricals. The loss of the intrinsic muscles of the hand also leads to a hyperextension deformity of the metacarpophalangeal (MCP) joints due to unopposed extension through the extrinsic finger extensors.
- The Bouvier test is used to assess if the extensor mechanism is functioning normally. The patient's MCP hyperextension is blocked and then he or she is asked to extend their PIP joints (**FIG 3**).
 - If the MCP flexion facilitates the patient's active PIP joint extension, the test is positive and the claw is defined as "simple," because by procedures to keep the MCP joints flexed, the PIP joints can extend via the extrinsic extensor tendons. However, the word "simple" is a misnomer because other than fusion of the MCP joints in flexion, all the soft tissue procedures applied to flex the MCP joints will stretch out over time.
 - If the patient cannot extend their PIP joints, the test is negative and the claw is "complex." Etiologies of a complex claw include central slip attenuation, central slip adherence to the PIP joint, and volar subluxation of the lateral bands.

IMAGING

- If the patient's clinical history is suspicious for arthritis, plain radiographs are

taken of the hand and wrist to assess the joints. Painful arthritic MCP and IP joints are better reconstructed with arthrodesis than with soft tissues procedures such as tendon transfers. Wrist arthrodesis is typically avoided to maintain wrist tenodesis.

FIG 3 • The Bouvier test is used to assess the extensor tendon mechanism in claw hand deformities. **A.** The examiner holds the MCP joints in flexion to passively correct the MCP hyperextension deformity. **B.** The patient is then asked to extend the PIP joints. If the patient is able to extend, the extensor mechanism is functioning properly and the claw is designated “simple,” as shown here. If the patient cannot extend the PIP joints, the claw is designated “complex.”

FIG 4 • Thermoplastic splints can be used to correct a claw hand deformity and unopposed thumb extension in combined median and ulnar nerve injuries. Here, the anticlaw splint corrects the patient's simple claw; correcting her MCP hyperextension permits active extension of her IP joints. The dorsal blocking thumb splint prevents the hyperextension deformity of the thumb at the carpometacarpal, MCP, and IP joints.

- Electrodiagnostic studies can be used to assess recovery following incomplete nerve injuries and after nerve repair to aid in planning for tendon transfers.
- Donor muscles can be tested if there is concern of their integrity. Donor muscles lose one medical research council grade of strength when transferred; grade 5 muscles are normal strength and are preferred as donors.

NONOPERATIVE MANAGEMENT

- Hand therapy is essential to maintain supple joints prior to reconstruction. A tendon transfer will not restore active ROM if the joint is stiff and incomplete passive ROM is present.
- Passive ROM should be optimized prior to surgery.
- If necessary, joint contracture release is performed prior to tendon transfer.
- Patients can be taught how to use wrist tenodesis to improve their hand function.
- Wrist flexion and extension can increase the amplitude of finger extension

and flexion by 2.5 cm, respectively.¹

- Preoperative splinting can be used to correct a patient's thumb and finger MCP joint hyperextension following a combined median and ulnar nerve injury (**FIG 4**).
- If the patient finds the splints helpful, surgical intervention—including thumb MCP arthrodesis and index, middle, ring, and small finger MCP volar capsulodesis or arthrodesis—is indicated.

SURGICAL MANAGEMENT

- Tension of the tendon transfer is critical for restoration of function while preventing the loss of ROM of other joints. In general, when suturing the tendon transfer, the joints are positioned as though the donor muscle is contracting and the transferred tendon is secured under tension.
- To minimize rupture rates, tendon transfers are best secured using three Pulvertaft weaves.⁴ The donor tendon is divided distally and the recipient tendon is divided proximally to facilitate adequate tendon weaving.
- The tendon transfer tension is set with one Pulvertaft weave and then wrist tenodesis is checked to ensure adequate passive ROM. Adjustments in tension can be made with the second and third Pulvertaft weaves.
- Tendon transfers can be performed in an end-to-end or end-to-side fashion.
 - End-to-end suturing facilitates a direct line of pull and is used if the recipient tendon is not expected to have any spontaneous recovery, for example, after complete denervation from an unrepaired nerve transection.
 - If the nerve has been repaired and some muscle recovery is expected, the tendon transfer is performed in an end-to-side fashion to augment existing function.
- A direct line of pull maximizes the power of the tendon transfer. If a direction change is unavoidable, the tendon should be passed around a fixed structure that behaves as a pulley, for example, the EIP tendon around the distal ulna to abduct the thumb.

Preoperative Planning

- When selecting a tendon for transfer, any resulting weakness must be considered. One tendon must remain intact to perform the donor's original function.
- Tendon gliding occurs best in a supple, stable soft tissue bed. If needed, scar contracture releases and flap reconstruction are performed prior to tendon

transfers to permit optimal tendon gliding and to minimize tendon adhesions.

- A stable platform with adequate bone and joint stability is required prior to tendon transfer. If required, arthrodesis of select joints is performed prior to tendon transfer.
- A thumb MCP arthrodesis can be helpful to correct severe thumb hyperextension following the loss of thumb flexion in a median nerve palsy. The MCP is fused in 15 to 20 degrees of flexion and 15 degrees of pronation using headless compression screws, a dorsal plate, or tension band wiring.
- Wrist fusion permits all three wrist extensors (ECRL, ECRB, ECU) to be harvested for transfer; however, this is not typically recommended because it will eliminate wrist tenodesis, which augments the excursion of the remaining tendons.

Positioning

- The patient is positioned supine with the arm extended on a hand table.
- A tourniquet is placed on the upper arm.

Approach

- Loupe magnification is helpful. Incisions are planned prior to inflation of the tourniquet.
- We prefer to use 3-0 polyester suture for our tendon transfers. Two sutures are placed to secure each Pulvertaft weave.

TECHNIQUES

■ Low Combined Median and Ulnar Nerve Palsy

Thumb Opposition

- In a low combined median and ulnar nerve injury, the ADM is denervated, but the FDS, PL, and EIP maintain their innervation and can be used as donor tendons for an opponensplasty. Only the EIP is available in high combined median and ulnar nerve palsies.
- The EIP is our preferred tendon transfer. It has minimal donor-site morbidity and has sufficient length to reach the APB insertion without a tendon graft.
- If the EIP is being used to restore another function of the hand following a

low median nerve injury, the ring finger FDS is our second choice for an opponensplasty.

- The ADM is only transferred in cases of congenital hypoplastic thumb or in combined median and radial nerve injuries.
- The PL is primarily used as an adjunct in elderly patients with severe carpal tunnel syndrome and thenar wasting. This tendon transfer provides more thumb abduction than true opposition.

Low Injury: Ring Finger FDS to APB Tendon Transfer

- The FDS is harvested and retrieved via transverse incisions first at the base of the proximal phalanx and then proximal to the carpal tunnel.
- A pulley is created by passing the FDS through a window in the transverse carpal ligament to reroute it obliquely across the palm.
- The FDS is secured to the APB at its insertion on the radial base of the proximal phalanx of the thumb.

Low or High Injury: EIP to APB Tendon Transfer

- The EIP is divided distally over the dorsal index finger MCP joint using a transverse or a V-shaped incision (**TECH FIG 1A**).

TECH FIG 1 • A. Two incisions are used over the dorsal hand and wrist for EIP harvest. The EIP is first identified over the index finger MCP joint using a transverse or a V-shaped incision. Next, it is identified over the dorsal wrist through a longitudinal incision distal to the extensor retinaculum. **B.** The EIP (*black arrows*) is divided for transfer over the index finger MCP joint. It is located ulnar to the EDC tendon (*red arrow*) in most patients. Next, it is retrieved over the dorsal wrist. **C.** The EIP is rerouted around the ulnar wrist, proximal to the pisiform, and then tunneled

subcutaneously to the APB insertion on the radial base of the proximal phalanx of the thumb. **D**. The EIP is secured to the APB tendon at its insertion using three Pulvertaft weaves secured with 3-0 polyester suture. **E,F**. The position of the right thumb is improved following opponensplasty, shown here at the end of the surgery (**E**) and at the 2-month follow-up visit (**F**).

- The EIP is located ulnar to the EDC in most patients (**TECH FIG 1B**); anatomic variations of the EIP and EDC over the MCP joint exist in 19% of patients.⁵
- The distal stump of the EIP can be sutured end to side to the index finger EDC tendon to prevent an extensor lag of the index finger.
- The EIP is retrieved over the distal wrist, using a longitudinal incision distal to the extensor retinaculum (**TECH FIG 1B**)
- It is then rerouted around the ulnar side of the hand, superficial to the FCU, using an incision proximal to the pisiform (**TECH FIG 1C**).
- After placement through the pulley, the EIP is tunneled through the subcutaneous tissue of the palm, volar to the neurovascular structures, to the APB tendon on the radial base of the proximal phalanx of the thumb.
- The EIP is sutured into the APB with the wrist in neutral and the thumb maximally palmarly abducted (**TECH FIG 1D-F**).
 - Setting tension is unnecessary because the EIP will barely reach the APB; wrist flexion may be required to suture the tendon in place.
 - After the tendon juncture has healed, the wrist is slowly brought to neutral position.

Thumb Adduction: ECRB to AdP With Tendon Graft

- Thumb adduction and pinch can be restored by transferring a tendon to the adductor pollicis (AdP) near its insertion on the ulnar base of the proximal phalanx of the thumb.
- The FDS from the ring finger or the ECRB are commonly transferred; the ECRB must be extended using a tendon graft to reach the AdP.

Low Injury: FDS to AdP Tendon Transfer

- In low median and ulnar nerve injuries, the FDS to the ring finger can be transferred to the AdP. The FDP to the ring finger is intact in these injuries and maintains finger flexion.
- The FDS is divided distal to the A1 pulley using an incision over the volar base of the ring finger proximal phalanx.
- The FDS is then retrieved through a second incision ulnar to the thenar crease at the base of the palm and is passed to the AdP insertion subcutaneously and sutured to the AdP through a third incision over the ulnar base of the thumb proximal phalanx.
- Tension is set with the wrist in neutral, the thumb adducted against the index finger, and the FDS at its resting length (**TECH FIG 2**).⁶

Low or High Injury: ECRB to AdP Tendon Transfer

- The ECRB is divided at its insertion over the dorsal base of the middle finger metacarpal.
- Using a second incision proximal to the extensor retinaculum, the ECRB is retrieved proximally.
- A third incision is used to expose the AdP over the ulnar base of the proximal phalanx of the thumb.
- A tendon graft is secured to the AdP and then passed through the intermetacarpal space between the index and middle finger metacarpals from the volar to the dorsal hand using a fourth incision longitudinally over the proximal third of the second intermetacarpal space.
 - This graft is passed deep to the flexor tendons and superficial to the AdP.
- The tendon graft is secured to the distal ECRB over the dorsal wrist with the wrist in neutral and the thumb adducted against the index finger (**TECH FIG 3**).

TECH FIG 2 • The ring finger FDS tendon is harvested at the base of the finger **(A)** and then rerouted for transfer to the adductor pollicis tendon on the ulnar proximal phalanx of the thumb **(B)** to restore thumb adduction following an ulnar nerve injury.

Index Finger Abduction: APL to First Dorsal Interosseous With Tendon Graft

- In 84% of people, the APL tendon has multiple tendinous slips⁷; up to 14 slips have been recorded.⁸ An accessory slip of APL can be harvested as a donor tendon in patients with multiple slips. In the 16% of patients with a single APL tendon, half of the APL tendon can be harvested longitudinally for transfer.
- A slip of the APL can be transferred to the first dorsal interosseous (DIO) tendon near its insertion on the radial index finger metacarpal to restore index finger abduction for pinch.
- A tendon graft is required for the APL to reach the first DIO tendon (**TECH FIG 4**).
 - The palmaris longus, plantaris, extensor digitorum longus (to the second, third, or fourth toes), or flexor digitorum longus (to the second, third, fourth, or fifth toes) can be used as a tendon graft.

TECH FIG 3 • Thumb adduction can be restored by transferring the ECRB to the adductor pollicis near its insertion on the ulnar base of the proximal phalanx of the thumb (*red arrow*), using a tendon graft. The graft first secured distally, passed through the second intermetacarpal space (*black arrow*), and then secured to the ECRB tendon proximally.

TECH FIG 4 • To restore index finger abduction and

pinch, a slip of the APL is transferred to the first DIO. A tendon graft is necessary for the APL to reach the insertion of the first DIO on the radial base of the index finger proximal phalanx.

- A slip of APL is harvested from its insertion on the radial aspect of the thumb metacarpal base using a longitudinal or V-shaped incision.
- A midlateral incision is made over the radial base of the index finger proximal phalanx to identify the first DIO.
- The tendon graft is secured to the first DIO and then passed proximally over the dorsal hand in the subcutaneous tissues to the proximal incision, where it is secured to the APL tendon.

Finger Clawing: FDS (Low Injury) or ECRL (High Injury) Tendon Transfer to the Lateral Bands of the Index, Middle, Ring, and Small Fingers

- For a simple claw, MCP joint hyperextension can be treated via static procedures such as volar MCP capsulodesis (the volar plate is detached and advanced proximally and secured with a bone anchor to the volar metacarpal to maintain the MCP in 45 degrees of flexion) (**TECH FIG 5**) or the Zancolli lasso (the FDS is divided over the distal proximal phalanx, removed from under the A2 pulley, turned proximally volar to the A1 pulley, and sutured to itself over the MCP joint).

TECH FIG 5 • A. This patient had a simple claw identified using the Bouvier test. MCP volar capsulodesis was performed for the index, middle, ring, and small fingers to correct the MCP hyperextension deformity. A volar incision was made over the volar MCP heads. The excess skin was marked for resection here. **B.** The index finger volar plate is shown here, with its proximal extent outlined with a purple marker. **C.** The proximal volar plate was elevated and then advanced proximally and secured to the metacarpal using a bone anchor to maintain the MCP in 45 degrees of flexion to correct the MCP claw hyperextension deformity. **D.** One bone anchor was

used to secure each proximal volar plate proximally to the volar metacarpal. The four bone anchors were placed **(E)**, and then each volar plate was advanced proximally and secured using the bone anchor suture to hold the MCP joints in 45 degrees of flexion **(F)**.

- Restoration of MCP joint flexion in a simple claw permits the patient to extend their IP joints through their extrinsic extensors (EDC, EIP, EDM). The main drawback of these soft tissues procedures is their tendency to stretch out over time.
- Our recommended long-term solution is to fuse the MCPJ in flexion (**TECH FIG 6**) or to perform a dynamic tendon transfer.
- In a complex claw, both MCP joint flexion and IP joint extension reconstruction are required. A dynamic tendon transfer is used. A four-tailed middle finger FDS (low injury) or ECRL (low or high injury) is commonly used as donor tendon for transfer in complex, and simple, claw hands.
 - If used, the ECRL must be extended with a tendon graft to enable it to reach the clawed digits.
- Tendon transfers in a simple claw are inserted into the A2 pulley to restore MCP joint flexion only.
- In a complex claw, the insertion is into the lateral bands over the proximal phalanx to restore both MCP joint flexion and IP joint extension.
- The tendon is passed from the distal palm, volar to the deep transverse metacarpal ligament, to the lateral bands of the affected digits.
- The tendon is secured to the ulnar lateral band for the index finger and to the radial lateral band for the middle, ring, and small finger.

TECH FIG 6 • A. To correct this patient's simple claw deformity of his index, middle, ring, and small fingers following a combined high median and ulnar nerve injury, MCP joint fusions were performed. The MCP joints could be passively flexed, but not actively. **B.** Dorsal incisions were used over the MCP joints. Two K-wires were used to fuse each of the patient's MCP joints in 45 degrees of flexion, as shown here on the PA radiograph (**C**), lateral radiograph (**D**), and lateral clinical photograph (**E**). The K-wires were removed 8

weeks postoperatively. The patient's MCP hyperextension deformity was corrected with MCP joint arthrodesis of the left index, middle, ring, and small fingers, shown here 4 months postoperatively with the fingers in extension **(F)** and flexion **(G)**.

Small Finger Abduction (Wartenburg Sign) Correction: EDM Tendon Transfer

- In a low median and ulnar nerve palsy, the abduction deformity of the small finger occurs due to the ulnar pull of the EDM on the small finger without opposition due to the deinnervation of the third palmar interosseous.
- To correct the ulnar deviation of the small finger, the ulnar half of the EDM is divided from its insertion on the dorsal proximal phalanx of the small finger and then passed volar to the deep transverse intermetacarpal ligament from the dorsal to the volar hand.
- If there is no clawing, the EDM can be sutured to the insertion of the radial collateral ligament of the small finger MCP joint.
- If there is clawing of the small finger, the EDM tendon is passed under the A2 pulley and sutured back to itself to correct the MCP hyperextension deformity.

■ High Combined Median and Ulnar Nerve Palsy

Thumb Flexion: BR to FPL Tendon Transfer

- To restore flexion of the thumb, the BR, ECRL, or ECRB can be transferred to the FPL.
 - We prefer to use the BR, it is the most expendable of these three tendons; its harvest results in minimal donor-site morbidity. This reserves the ECRL for transfer to the FDP for finger flexion and maintains the ECRB as the only remaining wrist extensor.
 - The ECRB is the preferred wrist extensor to preserve because it is the most centrally located over the dorsal wrist.
 - Preserving the ECRL only can lead to radial deviation of the wrist with extension. Similarly, preserving only the ECU can lead to ulnar deviation in extension.

- To transfer the BR, an incision is made over the volar-radial distal radius to identify the insertion of the BR onto the radial styloid as well as the FPL (**TECH FIG 7A**).
- The BR tendon is harvested distally with a 2-cm periosteal extension from the distal radius to increase its length (**TECH FIG 7B**).
- The superficial branch of the radial nerve must be carefully protected; this nerve is the only source of sensation to the hand in patients with combined median and ulnar nerve injuries.
- The BR is freed proximally off of the radius to maximize its excursion, moved volarly, and secured to the FPL proximal to the carpal tunnel (**TECH FIG 7C**).

TECH FIG 7 • A. In a patient with a high median nerve injury, an incision is designed over the volar-radial distal radius to identify the BR, FPL, and FDP. The BR is transferred to the FPL to restore thumb flexion. **B.** The ECRL (isolated on scissors) is identified for transfer to the FDP for finger flexion. (Pulling the ECRL causes wrist extension.) The BR (*arrow*) is identified for transfer to the FPL to restore thumb flexion. **C.** The BR is secured to the FPL proximal to the carpal tunnel, restoring thumb flexion.

- The tendon transfer tension is set with the elbow flexed at 90 degrees, the

wrist in 20 degrees of extension, the forearm fully pronated, and the thumb pulp and PIPJ of the index finger opposed.⁹

- The position of the elbow affects the degree of thumb flexion once the transfer has healed. When the elbow is extended, thumb flexion is stronger than when the elbow is flexed.

Finger Flexion: ECRL to FDP Tendon Transfer

- To restore finger flexion, the ECRL can be transferred to the FDP around the radial side of the wrist.
- An incision is made over the dorsal base of the index finger metacarpal to expose the ECRL insertion (**TECH FIG 8A**).
- The ECRL is divided near its insertion and then rerouted subcutaneously around the radial border of the forearm and sutured into the four FDP tendons proximal to the carpal tunnel using a second incision (**TECH FIG 8B**).
- The tendon transfer is secured to restore the flexion cascade of the digits; the tension is set progressively tighter from the index to the small finger.

Forearm Pronation: Rerouting the Brachioradialis Tendon

- Forearm pronation is lost following a high median nerve injury.
- To re-establish pronation, the biceps tendon insertion can be rerouted around the neck of the radius.¹⁰ Alternatively, the BR can be rerouted and the interosseous membrane can be released if tight.¹¹

TECH FIG 8 • A. Over the dorsal wrist, an incision is made to identify the ECRL. The ECRL is rerouted around the radial wrist and transferred to the FDP to restore finger flexion. **B.** The ERCL is secured to the FDP, restoring flexion of the index, middle, ring, and small fingers.

- We prefer to reroute the BR, it is less technically challenging than biceps rerouting and it provides greater active pronation than other techniques.
 - Biceps rerouting can cause an elbow flexion contracture.
- To reroute the BR, an incision is made over the volar distal third of the radius. The BR is elevated off the radius at its distal insertion and elevated proximally. It is extended 5 cm distally using Z-lengthening.
- The BR is then passed between the radius and ulna through the interosseous membrane, proximal to the pronator teres, from volar and ulnar to dorsal and radial.
- The elbow is placed in 90 degrees of flexion and the forearm is fully pronated. The BR tendon is secured to the dorsoradial distal third of the radius (**TECH FIG 9**).

Sensory Nerve Transfers

- In combined median and ulnar nerve injuries, all volar hand sensation is lost.
- To restore protective sensation, a branch of the superficial radial nerve can be transferred to the distal median nerve.
- Alternatively, a first dorsal metacarpal artery flap can be used to provide sensation to the volar thumb. A branch of the superficial branch of the radial nerve is contained within this innervated flap.

TECH FIG 9 • To restore forearm pronation, the BR can be rerouted around the radius. **A.** The BR tendon is extended 5 cm distally using Z-lengthening. The BR is elevated distally from its insertion on the radius, passed through the interosseous membrane (**B**), and then secured to the dorsoradial radius with the elbow flexed 90 degrees and the forearm in full pronation (**C**).

PEARLS AND PITFALLS

Physical findings

- Creating a chart is helping in determining an individualized surgical plan. The patient's main subjective functional complaints

	are listed in the first column. In the second column, the patient's objective physical examination deficits are listed. In the third column, the patient's intact, innervated tendons are documented; these are further classified into expendable tendons available for transfer and nonexpendable tendons that must be preserved to prevent donor-site morbidity. ■ The donor tendons are then matched to the functional deficits and the surgical plan is reviewed with the patient. ■ It is beneficial for the patient to meet with a hand therapist prior to tendon transfer surgery for preoperative teaching; rehabilitation protocols and expectations are reviewed.
Technique	■ Proper intraoperative tension setting and postoperative immobilization are necessary to optimize the outcomes of tendon transfers. ■ Wide-awake surgery using local anesthesia can facilitate intraoperative assessment of the tendon transfer tension.
Postoperative	■ The joints crossed by the tendon transfer are immobilized for 4 wk. ■ ROM exercises for the shoulder and unaffected joints of the upper extremity should be resumed immediately postoperatively to minimize stiffness.
Therapy	■ Some authors advocate for early active ROM exercises following tendon transfers secured with 3 Pulvertaft weaves to minimize adhesions. In these cases, tendon gliding exercises are started on postoperative day 2 under the guidance of a hand therapist.¹²

POSTOPERATIVE CARE

- Following a tendon transfer, we prefer to immobilize the affected joints for 4 weeks to permit tension-free tendon healing; casting or splinting is used.
- Above elbow immobilization is used in transfers crossing the elbow. For example, for the BR to FPL transfer, immobilization holds the elbow in 90 degrees of flexion and the wrist slightly flexed or in neutral. Following tendon transfers to correct clawing, the MCP joints are immobilized in flexion and the IP joints in extension.
- ROM exercises are started 4 weeks postoperatively, starting with active ROM and followed by passive ROM. Mobilizing one joint at a time minimizes tension on the tendon transfer.
- 6 weeks postoperatively, muscle retraining and resistance exercises begin.

- 8 weeks following surgery, strengthening exercises begin and splints are weaned.
- At 12 weeks postoperatively, free unrestricted activity can be resumed.

OUTCOMES

- The balance of the flexors and extensors of the hand and wrist is critical for optimal function.
- The transfer of radial nerve-innervated hand and wrist extensors to restore hand and wrist flexion aids in restoring the function of the hand by re-establishing active hand and wrist flexion while weakening hand and wrist extension, improving the overall balance of the hand and wrist.

COMPLICATIONS

- Thorough discussion with the patient, careful physical examination, and thoughtful planning are required to optimize the function of the upper extremity following combined median and ulnar nerve injuries.
- The patient is counseled that his or her volar and dorsoulnar hand will remain insensate following tendon transfers. Worse outcomes are seen in patients with decreased sensation compared to those with intact sensation. Following sensory nerve injury, visual and auditory cues are required to permit the patient to use their injured hand; tactile sensory feedback is absent. Sensory nerve transfers can be performed to restore protective sensation. Ideally, nerve repair at the time of the injury is performed to permit motor and sensory recovery over time.
- Transferred tendons can rupture if placed under excess tension, if inadequately sutured during surgery, and if not sufficiently immobilized after surgery. If rupture occurs, immediate exploration and primary repair are recommended.
- Adhesions frequently form where tendons cross each other and in scarred tissue beds. Frequent, intensive hand therapy is used to optimize passive ROM in these cases. If passive ROM exceeds active ROM, a tenolysis may be beneficial. Tenolysis is performed no sooner than 3 months following the tendon transfer. Patient compliance is critical; daily hand therapy exercises are started 2 days after tenolysis to maintain intraoperative active ROM gains.
- Multiple long incisions are used for tendon transfers; patients must be counseled about postoperative scarring prior to reconstruction. Postoperatively, scar massage and sun avoidance are recommended for scar management.

35 Distal Anterior Interosseous Nerve Transfer to Motor Branch of Ulnar Nerve

CHAPTER

Shelley S. Noland and Jason H. Ko

DEFINITION

- Ulnar nerve palsy severely limits hand function with loss of dexterity, pinch and grip strength weakness, and claw formation.
- Ulnar-innervated intrinsic muscle recovery after high ulnar nerve injury (above elbow) is poor.
- Distal transfer of the anterior interosseous nerve (AIN) to the motor component of the ulnar nerve can preserve motor endplates and restore motor function.

ANATOMY

- Ulnar nerve
 - After exiting the cubital tunnel, the ulnar nerve enters the forearm between the two heads of the flexor carpi ulnaris (FCU).
 - It travels between the FCU and flexor digitorum profundus (FDP) muscles and gives off the dorsal sensory branch 9 cm proximal to the wrist crease.
 - At the Guyon canal, it enters the hand and divides into the deep motor branch and the sensory branch.
 - Internal topographical anatomy
 - Topographical anatomy is critical to the success of this procedure.
 - The ulnar nerve has a discrete fascicular pattern.
 - At the level of the mid-forearm, the three components are the ulnar-sided sensory component (dorsal sensory branch), the middle motor component (intrinsic motor function), and the radial-sided sensory component (digital ulnar sensation) (**FIG 1**).

■ Median nerve

- After exiting from underneath the lacertus fibrosus, the median nerve travels through the pronator teres.
- It courses between the flexor digitorum superficialis (FDS) and the FDP and gives off four motor branches in the proximal forearm.
- It enters the hand at the carpal tunnel and divides into the recurrent motor branch and sensory branches.
- Anterior interosseous nerve
 - Branches from the median nerve 3 cm distal to the intercondylar line
 - Contains fascicles to the flexor pollicis longus (FPL), FDP (index and middle finger), and pronator quadratus (PQ)
 - Exits the median nerve on the dorsal radial aspect (**FIG 2**)

FIG 1 • Internal topography of the ulnar nerve. A, anterior; P, posterior; L, lateral; R, radial; M, medial; U, ulnar.

nerve distributions.

- Perform full motor exam of bilateral upper extremities by documenting strength in relevant muscles, clawing of the fingers, intrinsic atrophy/wasting, and presence of Froment (thumb interphalangeal flexion with pinch) or Wartenberg signs (abducted posture of small finger).
- Perform provocative maneuvers including elbow flexion test and compression at the Guyon canal.

IMAGING

- Obtain nerve conduction studies (NCS) and electromyography (EMG) to help with localization of lesion and to assess severity of ulnar neuropathy.
- NCS may demonstrate a conduction block at the cubital tunnel or Guyon canal.
- EMG can identify the presence and quality of fibrillations, positive sharp waves, and motor unit potentials.
- In setting of trauma, traditional x-rays are recommended to evaluate for fracture, dislocation, or foreign body.
- In setting of tumor, formal imaging studies such as CT or MRI are warranted as appropriate.

DIFFERENTIAL DIAGNOSIS (OPTIONAL)

- Cervical radiculopathy
- Cubital tunnel syndrome
- Guyon canal compression
- Shoulder injury
- Thoracic outlet syndrome
- Polyneuropathy
- Other systemic neuropathy

SURGICAL MANAGEMENT¹⁻³

- Distal AIN to motor branch of ulnar nerve transfer should be considered in patients with isolated high ulnar nerve injuries or lesions (above elbow).
- Patient must have intact median nerve and AIN function.

Preoperative Planning

- Patient counseling regarding the timeline of recovery is critical (1 mm/d).
- Need to coordinate care with a hand or physical therapist for postoperative

motor re-education.

Positioning

- The patient is positioned supine on operating table with the affected arm extended and supinated on an armboard.

Approach

- The entire procedure is completed through a single incision designed longitudinally or zigzag over the course of the FCU and ulnar neurovascular bundle in the distal 1/3 of the volar forearm (**FIG 3**).

FIG 3 • Surgical approach for AIN to ulnar motor nerve transfer.

TECHNIQUES

■ Distal Exposure Including Identification of the Motor Component of the Ulnar Nerve

- A longitudinal incision is made in the distal 1/3 of the volar forearm over the course of the flexor carpi ulnaris (FCU) and ulnar neurovascular bundle including a short zigzag segment across the wrist crease.
- The pisiform and hook of the hamate are marked, and a longitudinal incision between them is made to approach the Guyon canal. Sharply dissect the overlying fascia at the level of the wrist crease, exposing the ulnar neurovascular bundle.

- The ulnar neurovascular bundle is identified and retracted ulnarly.
- The deep motor branch is released by dividing the leading edge of the hypothenar musculature off of the hook of the hamate.
- The motor branch is then identified and traced proximally. Either manual or visual neurolysis can be performed to identify the motor component of the ulnar nerve 9 cm proximal to the wrist crease.
- The motor component of the ulnar nerve is marked with a vessel loop 9 cm proximal to the wrist crease (**TECH FIG 1**).

TECH FIG 1 • Identification of the motor component of the ulnar nerve (vessel loop).

■ Proximal Exposure Including Identification of the Anterior Interosseous Nerve

- Through the same incision, identify the finger flexors and retract them radially to identify the pronator quadratus (PQ) muscle. Some muscle fibers of the flexor digitorum profundus (FDP) may have to be released to gain better visualization of the proximal PQ and anterior interosseous nerve (AIN).
- At the proximal edge of the PQ, identify the AIN entering the muscle.
- Carefully divide the PQ with bipolar cautery for 1 to 2 cm (proximal to distal) superficial to the AIN to maximize AIN length for transfer (**TECH**

FIG 2).

- Divide the AIN distally just prior to its branching point, which is typically at the halfway point of the PQ.

TECH FIG 2 • Division of the pronator quadratus to reveal the distal extent of the AIN (upper *blue* background).

■ End-to-End Transfer of the AIN to the Motor Component of the Ulnar Nerve

- Transfer the AIN ulnarly across the PQ to the ulnar nerve 9 cm proximal to the wrist crease (**TECH FIG 3A**).
- Ensure adequate length to perform transfer with no tension.
- Divide the motor component of the ulnar nerve as proximally as necessary to ensure adequate length to perform transfer with no tension.
- Intrafascicular dissection of the ulnar motor fascicle distally will allow for a tension-free coaptation.
- Perform neurorrhaphy with a microscope using 9-0 nylon suture (**TECH FIG 3B**).
- Evaluate the neurorrhaphy site while performing a full pronation-supination arc to ensure no tension at any forearm position.
- Close skin in standard fashion, and either a soft dressing or volar wrist splint

is placed.

TECH FIG 3 • **A.** Division of the AIN. **B.** End-to-end neurorrhaphy of AIN to motor component of ulnar nerve.

■ Reverse End-to-Side AIN to Ulnar Motor Nerve Transfer⁴

- Consider reverse end-to-side transfer in patients in whom ulnar nerve recovery is ultimately expected. Also, in high ulnar nerve injuries where distal intrinsic recovery is possible, the distal reverse end-to-side AIN nerve transfer can be performed to help “babysit” the motor endplates in the hand until the more proximal regenerating axons can reach the hand.
- When performing a reverse end-to-side nerve transfer, the skin incision should be longer, and the ulnar nerve exposure should be more proximal. To obtain a tension-free reverse end-to-side nerve transfer, the AIN will have to be transferred more proximally to reach the ulnar nerve than in an end-to-end transfer.
- Instead of dividing the ulnar motor component, create epineurial and perineurial windows in the motor component of the ulnar nerve.
- Transfer the AIN to this epineurial/perineurial window ensuring no tension.
- Perform neurorrhaphy of the AIN to the side of the ulnar motor component with a microscope using 9-0 nylon suture (**TECH FIG 4**).
- Evaluate the neurorrhaphy site while performing a full pronation-supination arc to ensure no tension at any forearm position.

- Close skin in standard fashion, and either a soft dressing or volar wrist splint is placed.

TECH FIG 4 • A,B. End-to-side neurorrhaphy of AIN to motor component of ulnar nerve.

PEARLS AND PITFALLS

Nerve transection	■ Remember that the Donor nerve (AIN) is always cut Distal and the recipient nerve (ulnar motor branch) is always cut proximal.
Guyon canal release	■ It is important to perform a full Guyon canal release to prevent a distal conduction block on the recovering nerve.
Reverse end-to-side transfer	■ Consider a reverse end-to-side transfer in patients in whom ulnar nerve recovery is ultimately expected.
Tension	■ Ensure no tension on neurorrhaphy site while observing a full pronation-supination arc.
Postoperative rehabilitation	■ Ensure that you have a hand therapist knowledgeable in motor re-education for optimal outcomes.

POSTOPERATIVE CARE

- If a splint was used, the postoperative splint can be removed and gentle range of motion can be initiated 1 week after surgery.

- Once postoperative pain has subsided at 3 to 4 weeks, the patient begins motor re-education under the care of a knowledgeable hand therapist.

OUTCOMES

- There are limited outcomes data for this procedure, but most case series report return of intrinsic function within 1 year of surgery.

COMPLICATIONS

- The most common complications are infection, bleeding, and lack of reinnervation of the intrinsic musculature.

36 Nerve Transfers for High Radial Nerve Palsy

CHAPTER

Shelley S. Noland and Jason H. Ko

DEFINITION

- High radial nerve palsy limits hand and wrist function with loss of wrist, finger, and thumb extension.
- The presence of a wrist drop significantly decreases finger flexion power and grip strength.
- The inability to open the hand to initiate grasp makes tasks of manual dexterity difficult.
- Distal transfer of median-innervated nerve branches to branches of the radial nerve can preserve motor endplates and restore motor function.

ANATOMY

- Radial nerve
 - Originates from the posterior cord of the brachial plexus
 - Courses between the humerus and the triceps and innervates the triceps muscle
 - Travels in the spiral groove posterior to the humerus and exits through the lateral intermuscular septum about 10 cm proximal to the lateral epicondyle
 - Passes between the brachialis and brachioradialis (BR) and gives off the following branches:
 - BR muscle branch
 - Extensor carpi radialis longus (ECRL) muscle branch (at the level of the interepicondylar line)
 - Enters the forearm by passing anterior to the lateral epicondyle and gives off the following branches (**FIG 1**):
 - Radial sensory nerve (RSN) branch, which courses underneath the BR

- Extensor carpi radialis brevis (ECRB) muscle branch (about 3 cm distal to the interepicondylar line)
- Supinator muscle branches (1–2; just proximal to the leading edge of the supinator)
- Continues as the posterior interosseous nerve (PIN) and innervates all hand and wrist extensors
- Median nerve
 - Originates from the medial and lateral cords of the brachial plexus
 - Courses anterior and medial to the brachial artery
 - Travels between the brachialis muscle and the medial intermuscular septum
 - Gives off the pronator teres (PT) muscle branch at the level of the interepicondylar line
 - Courses under the lacertus fibrosus, through the superficial and deep heads of the (PT), and underneath the tendinous arch of the flexor digitorum superficialis (FDS) and gives off the following branches (see **FIG 1**):

FIG 1 • Anatomy of the median and radial nerves in the

forearm.

- FDS muscle branches (2–3) from the ulnar side of the median nerve
- Flexor carpi radialis (FCR) muscle branch
- Palmaris longus (PL) muscle branch (if PL is present)
- Anterior interosseous nerve (AIN) from the dorsal radial side of the nerve
 - Branches 3 cm distal to the intercondylar line
 - Contains fascicles to the flexor pollicis longus (FPL), flexor digitorum profundus (FDP; index and middle finger only), and pronator quadratus (PQ)
- Palmar cutaneous branch in distal forearm
- Enters the hand at the carpal tunnel and divides into the recurrent motor branch and sensory branches

PATIENT HISTORY AND PHYSICAL FINDINGS

■ History

- Obtain history of trauma, tumor, or other injury to the affected extremity.
- Ask location, timing, frequency, and duration of sensory symptoms including numbness and tingling.
- Rule out other causes of symptoms such as cervical spine, shoulder, or brachial plexus issues.
- Elicit a history of the etiology of the radial nerve palsy.
- Determine the timeline of injury.

■ Physical examination

- Perform full motor exam of bilateral upper extremities.
- Assess for a Tinel sign along the course of the radial nerve.
- Perform a full motor and sensory examination of the entire affected extremity.
 - Determine the level of the injury.
 - If the patient has a wrist drop, it is likely a high radial nerve palsy occurring prior to the innervation of the ECRL and ECRB (**FIG 2**).
 - If the patient can extend the wrist, he or she likely has a PIN palsy with preservation of ECRL and ECRB function.
 - Perform full sensory exam of bilateral upper extremities documenting 2-point discrimination and/or Semmes-Weinstein monofilament testing in all

nerve distributions.

- Sensory disturbances in radial nerve lesions typically involve the dorsal radial aspect of the thumb and hand.
- Ensure that the injury is isolated to the radial nerve.
 - Test and record function in your potential median-innervated donor nerves including branches to the FCR, FDS, and PL.
 - Test and record function in the median-innervated muscles that may need to be used for tendon transfers in the event there are no nerve transfer options including the PT, FCR, and PL.

IMAGING

- Obtain electrodiagnostic studies to assist with localization of the injury and to assess severity of the radial nerve palsy.

FIG 2 • Example of wrist drop.

- EMG can identify the presence and quality of fibrillations, positive sharp waves, and motor unit potentials. This can be followed over time to determine reinnervation status.
- In setting of trauma, traditional x-rays are recommended to evaluate for fracture, dislocation, or foreign body.
- In setting of tumor, formal imaging studies such as CT or MRI are warranted as appropriate.

SURGICAL MANAGEMENT¹⁻³

- Patients should be monitored from the time of injury for reinnervation of wrist, finger, and thumb extensors.
- Patients with no evidence of clinical or electrical reinnervation at 6 to 9 months should be considered for nerve transfers. Alternatively, tendon transfers can be performed in a delayed fashion and will be discussed in Chapter 39 (**FIG 3**).
- The most common nerve transfers for high radial nerve palsy are
 - FCR to PIN
 - FDS to ECRB
 - Lateral antebrachial cutaneous nerve (LABC) to RSN
- Typically, there are redundant motor branches to the FCR and FDS, so using a single-donor nerve branch will still leave some function of the FCR and FDS, which can still be used to power a tendon transfer if the nerve transfer is not sufficient.

Preoperative Planning

- Patient counseling regarding the timeline of recovery after nerve transfers is critical (1 mm/d).
- Need to coordinate care with a hand or physical therapist for postoperative motor re-education

Positioning

- Patient is positioned supine with the arm extended on a hand table.
- Tourniquet can be used if donor exposure and identification can be accomplished within 30 to 40 minutes.
 - After 30 to 40 minutes, tourniquet neurapraxia may preclude the use of nerve stimulation.

FIG 3 • Algorithm for the management of high radial nerve palsy. Reprinted from Pet MA, Lipira AB, Ko JH. Nerve transfers for the restoration of wrist, finger, and thumb extension after high radial nerve injury. *Hand Clin.* 2016;32(2):191-207 with permission.

TECHNIQUES

■ Identification, Decompression, and Dissection of the Median Nerve

- A straight incision from the lateral antecubital fossa along the medial aspect of the BR to the midpoint of the forearm is utilized, which provides exposure of median and radial nerves (**TECH FIG 1A**).
- Identify and protect the LABC nerve that runs with the cephalic vein.
 - Identify and retract the BR to identify the RSN and radial vessels beneath (**TECH FIG 1B**). This provides visualization of the PT tendon.
- If PT to ECRB tendon transfer will be performed, the skin incision is

extended distally to visualize the insertion of the PT on the radius.

- The insertion of the PT is elevated with a strip of periosteum as distally as possible, and subperiosteal dissection is performed distal to proximal at this stage for later tendon transfer.
- Because it takes 6 to 9 months to begin to see motor recovery after these nerve transfers, the PT to ECRB tendon transfer acts as an immediate treatment for wrist drop, which can be quite debilitating for patients.
 - This tendon transfer works well and acts as an internal splint until motor recovery occurs.
- If the PT to ECRB tendon transfer is not performed, step-lengthening of the PT tendon should be performed at this point.
 - This allows the superficial head of the PT to be reflected medially, exposing the deep head of the PT.
- Release the deep head of the PT to expose and decompress the median nerve in the proximal forearm.
- Identify and release the tendinous edge of the FDS to further decompress the median nerve and allow direct visualization of the nerve branches.
- Identify the median nerve and dissect it distally to identify the following branches (**TECH FIG 1C**):
 - PT, PL, FCR, FDS, AIN
 - Use of a nerve stimulator will help confirm branch identity.
 - It is helpful to loop each branch with a vessel loop in preparation for later transfer.

TECH FIG 1 • **A.** Approach for median to radial nerve transfers. **B.** Identification of radial sensory nerve. **C.** Identification of median nerve branches, including flexor carpi radialis (FCR) and flexor digitorum superficialis (FDS), along with radial nerve branches, including extensor carpi radialis brevis (ECRB) and posterior interosseous nerve (PIN).

■ Identification, Decompression, and Dissection of the Radial Nerve

- Retract the BR laterally and follow the RSN proximally until the main radial nerve is identified.
- Divide the transverse radial recurrent vessels that overlie the radial nerve (“leash of Henry”).
- Dissect the radial nerve distally and identify the following branches (**TECH FIG 2**).
 - ECRB branch: This branch is small and directly radial to the RSN.

- PIN branch: This branch is larger and radial to the ECRB branch. This branch dives deep to the supinator muscle.
- Use of a nerve stimulator will help confirm branch identity.
- It is helpful to loop each branch with a vessel loop in preparation for later recipient of nerve transfer.
- Release the tendinous leading edge of ECRB and supinator muscles (arcade of Frohse).
- This is important for maximal mobilization of recipient nerves.

TECH FIG 2 • Coaptation of flexor carpi radialis (FCR) to posterior interosseous nerve (PIN) and flexor digitorum superficialis (FDS) to extensor carpi radialis brevis (ECRB) nerve transfers.

■ Mobilization and Transection of the Donor and Recipient Nerves

- Mobilize FCR, FDS, and LABC branches as distally as possible and transect them distally.
 - This will facilitate a tension-free neurorrhaphy.
- Mobilize PIN, ECRB, and RSN branches as proximally as possible and transect them proximally.
 - This will facilitate a tension-free neurorrhaphy.

■ Transfer FCR to PIN

- Oppose the FCR (donor) and the PIN (recipient) to facilitate a tension-free repair (see **TECH FIG 2**).
- Perform end-to-end coaptation using a microscope and 9-0 nylon.
- May use two or three sutures followed by fibrin glue
 - This will minimize trauma and foreign body reaction.
- Perform complete wrist and elbow range of motion to confirm that no tension is present in any arm or wrist position.

■ Transfer of FDS to ECRB

- Oppose the FDS (donor) and the ECRB (recipient) to facilitate a tension-free repair (see **TECH FIG 2**).
- Perform end-to-end coaptation using a microscope and 9-0 nylon.
- May use two or three sutures followed by fibrin glue.
 - This will minimize trauma and foreign body reaction.
- Perform complete wrist and elbow range of motion to confirm that no tension is present in any position.

■ Transfer of LABC to RSN (Optional)

- Oppose the LABC (donor) and the RSN (recipient) to facilitate a tension-free repair (**TECH FIG 3**).
- Perform coaptation using a microscope and 9-0 nylon.
- May use two or three sutures followed by fibrin glue
 - This will minimize trauma and foreign body reaction.
- Perform complete wrist and elbow range of motion to confirm that no tension is present in any position.

TECH FIG 3 • Example of lateral antebrachial cutaneous nerve (LABC) to radial sensory nerve (RSN) transfer.

■ Tendon Transfer of PT to ECRB (Optional)

- The ECRB tendon is identified in the surgical field.
- The previously elevated distal PT insertion with periosteal strip is identified and dissected proximally.
- An end-to-side tendon transfer of the PT to ECRB is performed using three or four Pulvertaft weaves and secured with 3-0 braided, nonabsorbable suture (**TECH FIG 4**).

TECH FIG 4 • Example of pronator teres (PT) to extensor carpi radialis brevis (ECRB) tendon transfer (arrow).

PEARLS AND PITFALLS

Preservation of critical branches

- It is critical to preserve the pronator teres and anterior interosseous nerve branches during this operation.

Pronator teres step-lengthening

- This is critical to help with identifying the median nerve and its branches in the proximal forearm.

Decompression of involved nerve branches

- Decompression of involved nerves and branches facilitates axonal regeneration.

Nerve transection

- Remember that the donor nerve is always cut distal and the recipient nerve is always cut proximal.

POSTOPERATIVE CARE

- Immediately postoperatively, if no tendon transfer has been performed, a soft dressing is applied, allowing for free motion of the elbow, wrist, and fingers.

- If the PT to ECRB tendon transfer has been performed, a short-arm plaster splint should be applied to stabilize the wrist in an extended position.
- At 2 weeks postoperatively, this should be transitioned to a short-arm cast for an additional 2 weeks.
- If no tendon transfer has been performed, 2 weeks postoperatively, initiate early motor re-education, edema control, scar management, and gentle ROM.
- It is important to begin motor re-education before reinnervation.

OUTCOMES

- There are limited outcomes data for this procedure, but most case series report return of intrinsic function within 1 year of surgery.

COMPLICATIONS

- The most common complications are infection, bleeding, and lack of reinnervation of the radial-innervated musculature.

Section IX: Tendon Conditions

37 Acute Repair of Flexor Tendon Injuries

CHAPTER

Jacques A. Machol IV, Neal Chen, and Kyle R. Eberlin

DEFINITION

- Flexor tendon repair has evolved substantially over time. Flexor tendon repair balances strong tendon healing against adhesion formation. There is a complex interplay between tendon repair technique and rehabilitation that dramatically affects the outcome of flexor tendon repair.
- Biomechanical strength of suture technique
 - The strength of most initial tendon repairs ranges between 30 and 150 N.¹
 - The repair may experience forces up to 50 N during rehabilitation.²
 - The strength of flexor tendon repair is related to the number of core strands crossing the repair site.
 - Strength of repair is related to suture caliber.
 - Locking sutures provide greater biomechanical strength than do grasping sutures.
 - Epitendinous sutures provide substantial strength to the tendon repair.
 - Venting of the A2 or A4 pulley can decrease friction in the flexor tendon system and improve clinical results.
 - Similarly, some surgeons elect to excise a slip of the flexor digitorum superficialis (FDS) tendon to reduce bulk and gliding resistance.
- Rehabilitation
 - During the first 1 to 3 weeks, up to 50% of initial repair strength is lost if a tendon is immobilized.

- Early motion yields superior tensile strengths compared to delayed motion or immobilization.
- Pyramidal rehabilitation protocols incorporating advancing force and excursion are also being used that are even more physiologically demanding than prior early active motion protocols.
 - Pyramidal protocols begin with the lowest stress force exercises and then progressively advance forces as needed in order to overcome adhesion formation.

ANATOMY

- The FDS muscle belly lies in the superficial anterior compartment of the forearm. It originates from the medial epicondyle of the humerus in the common flexor tendon and also has attachments on the oblique line of the radial head and the proximal ulna. This muscle belly is innervated by the median nerve.
- The FDS tendon to the small finger is congenitally absent in up to 7% of the population.³
- The FDS decussates at Camper chiasm. Here, it envelops the flexor digitorum profundus (FDP) and inserts with a 180-degree rotation.
- The FDP originates from the anteromedial surfaces of the ulna, the interosseous membrane, and the deep forearm fascia. It is located dorsal to the FDS.
 - The anterior interosseous nerve of the median nerve in most cases innervates the index and long fingers.
 - The ring and small finger FDPs are innervated by the ulnar nerve.
 - The long, ring, and small FDP tendons share a common muscle belly.
 - The FDP of the index finger is usually separate.
- The common muscle bellies of the long, ring, and small fingers are important clinically because of the quadriga phenomenon. If one of these tendons is shortened, the change in excursion may limit the ability of the other tendons to flex fully.
- The flexor tendons have limited blood supply. They are nourished by segmental, penetrating arteries via the vincular vasculature (**FIG 1A**).
- The digital nerve is volar to the digital artery in the finger.
- A complex pulley system in the distal palm and digits brings the tendons close to the bone, thus increasing the overall mechanical advantage (**FIG 1B**).

- The A5 and C3 pulley systems may require division in zone 1 injuries.
- Flexor tendon injuries are divided into five zones labeled from distal to proximal:
 - Zone 1: Insertion of the FDP to the insertion of the FDS. These are commonly referred to as “jersey fingers.” The Leddy-Packer classification is used for zone 1 FDP avulsion injuries:
 - Type 1: The tendon retracts into the palm; surgery is recommended within 7 to 10 days.
 - Type 2: The FDP is at the proximal interphalangeal (PIP) and held by the vinculum; surgery is recommended within 2 to 3 weeks.
 - Type 3: The FDP is located at the A4 pulley and held by the distal phalanx bone fragment; surgery within several weeks may be acceptable, but earlier repair is advocated.
 - It is possible to have a distal phalanx fracture with tendon avulsion off of the bone fragment. These are commonly referred to as Leddy-Packer 4 injuries.

FIG 1 • A. Insertion of flexor digitorum profundus (FDP) and flexor digitorum superficialis (FDS) with vinculum longus (VL) and vinculum brevis (VB). **B.** Flexor tendon

pulley systems. A indicates annular, and C indicates cruciate.

- Zone 2: FDS insertion to the distal palmar crease (A1 Pulley)
 - Much of the study of tendon repair has focused on zone 2 injuries, also termed “no man’s land.”
 - This area is particularly difficult to repair because of the complexity of the tendons, pulleys, and blood supply in this region.
- Zone 3: Distal palmar crease to the carpal tunnel
- Zone 4: Carpal tunnel
- Zone 5: Wrist to the forearm

PATHOGENESIS

- Zone 1 flexor tendon injuries often are caused by resistive flexion. The ring finger is slightly more prominent than other digits during midflexion. It is theorized this is why jersey fingers affect the ring finger more often than they do other digits.
- Flexor tendon injuries are typically caused by sharp lacerations but may also occur after crush injuries.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The digital cascade should be inspected. The index through small digits should gently point to the scaphoid tubercle.
- A passive tenodesis maneuver can be performed. All digits should flex with wrist extension. If a flexor tendon is injured, it will not reciprocally flex with wrist extension.
- FDP is tested by restricting the metacarpophalangeal (MCP) and PIP joints in extension and asking the patient to flex the digit at the distal interphalangeal (DIP) joint.
- FDS is examined by restricting the adjacent digit(s) in extension and asking the patient to flex the digit. This maneuver utilizes the quadriga effect to limit excursion of the FDP, thereby relying on the FDS to flex the digit at the PIP joint.
- It is important to recognize that incomplete injuries may be missed on clinical exam.
- Sensation of the ulnar and radial digital nerves of each digit should be

evaluated. Static two-point discrimination is beneficial in evaluating nerve transection.

- Vascularity of the digit can be evaluated by capillary refill. A digital Allen test can also be beneficial if a single digital vessel injury is suspected.

IMAGING

- Plain radiographs should be obtained to evaluate for underlying fracture or foreign body.
 - These may also be used to locate the distal end of FDP if there is a bony avulsion associated with a jersey finger.
- Ultrasound or MRI can be used if there is question regarding tendon integrity that is not apparent on clinical exam.
 - These studies are not routinely obtained in acute, penetrating trauma.

DIFFERENTIAL DIAGNOSIS

- Usually, the diagnosis is unambiguous based on history and clinical examination, but injuries may be heterogeneous.
- Tendon injuries are often accompanied by digital nerve or arterial injuries.

SURGICAL MANAGEMENT

- There are a large number of tendon repair techniques. We will describe those techniques we most commonly use: Tajima, modified Kessler, locking cruciate (Adelaide), and modified Becker (MGH suture).
 - The Tajima or modified Kessler is biomechanically weaker than the other two suture configurations; however, this suture construct is reasonable in zone 3 to 5 repairs where early motion is not as crucial. We use this suture in cases that may be time dependent, such as multiple digit replantations, to expedite the time expended for tendon repair.
 - The locking cruciate offers benefits of a single knot that is buried within the tendon.
 - The modified Becker is mechanically stronger than the locking cruciate but requires a larger exposure. One disadvantage is that knots are external to the tendon and may increase the bulk of the repair.
- We perform an epitendinous suture in our zone 2 repairs. With a modified Becker suture, some surgeons place half of the epitendinous suture first before inserting the core sutures.

Preoperative Planning

- Obtain a preoperative digital neurologic and vascular exam to evaluate for injury as these structures are often repaired during the same operative period.
- Wide-awake surgery (WALANT) is helpful to evaluate tendon repair and gliding intraoperatively.
- A pediatric feeding tube is helpful for tendon retrieval and passage through the intact proximal sheath when the tendon is retracted.
 - One trick is to place the feeding tube in a freezer to improve the stiffness of the catheter. There are also various funnels that can be used to help pass the tendon.

Positioning

- The patient is positioned supine with the arm abducted to 90 degrees on a padded hand table.
- A well-padded tourniquet, if used, should be placed on the biceps to avoid compressing the flexor tendon muscle bellies. Excess forearm pressure will affect resting tendon tension.

Approach

- The use of existing lacerations with extensions via Bruner-type incision or midaxial incision will provide adequate exposure for repair.
 - If skin viability/coverage is in question, a midaxial incision is preferable to avoid the acute angle at the tip of the flap that can cause tip flap necrosis and expose the underlying repair.
- It is important to get adequate visualization of the laceration. We commonly expose from the MP joint flexion crease to the DIP flexion crease for a transverse laceration. We find that a large exposure aids in performing an adequate tendon repair and generally does not hamper outcomes.
- Consider extending the incision more proximally, by including a separate carpal tunnel incision if there is concern for retraction into the palm (ie, Leddy-Packer type 1).
- One should preserve most of the pulley system in a way to prevent bowstringing.
 - Some authors will vent the A2 or 4 pulley systems by partially releasing the pulleys to facilitate gliding of repaired tendon and have reported no mechanical problems with this technique.

TECHNIQUES

■ Zone I Repair

Primary Suture

- There should be at least 1 cm of distal tendon stump to use this technique (**TECH FIG 1A**).
- The proximal FDP tendon may or may not be retracted.
- If retracted, it should be passed back through the pulley system. This may be completed using a tendon passer or pediatric feeding tube or via suture to pull through the pulley system.
- Sometimes, the pulley system is very tight, and it is helpful to use a funnel-type device to pull the tendon distally.
 - The funnel helps the tendon end enter the pulley system. We have found this particularly helpful to minimize fraying of the passed tendon, limiting trauma to the tendon and optimizing tendon gliding.
- Wrist and digit flexion will help tendon retrieval.
- A 25-gauge needle is used to maintain the location of the tendon by preventing retraction.
- After pulling the tendon into the repair site, the proximal tendon is skewered with the needle to the tendon sheath to stabilize the tendon (**TECH FIG 1B**).

Pull-Through Button

- The preparation of the proximal tendon is the same as previously described.
- Repair using a pull-through button is indicated if there is no distal stump or bone fragment for fixation.
 - The insertion site is prepared with a small curette to roughen a portion of the volar cortical bone to encourage tendon to bone healing.
 - A 3-0 nonabsorbable suture that can glide such as Prolene is placed at least 1 cm from the distal edge of the proximal tendon in a Bunnell weave fashion. Prolene is used because this suture will slide and can be pulled out readily during button removal.

TECH FIG 1 • Zone I repair: primary suture. **A.** Zone 1 flexor digitorum profundus laceration. **B.** Primary repair completed.

TECH FIG 2 • Zone I repair: pull-through button. **A.** Modified Kessler suture on tendon end (two Keith needles are used to pass the suture through the bone end, not shown). **B.** Suture passed through the distal phalanx. **C,D.** Suture tied over gauze dressing and button.

- Two Keith needles are then passed through the nail. There are two methods of passing the needles:
 - Some authors pass the needles through bone. They are passed using a drill

parallel to each other through the distal phalanx insertion site through the nail plate just distal to the lunula. It is important to pass the K-wires in a relatively acute angle relative to the phalanx (approximately 30 degrees). If they are passed too perpendicular to the nail and too distally, the DIP may assume an excessively flexed position (**TECH FIG 2A,B**).

- Other surgeons pass needles around the distal phalanx as an alternative to transosseous sutures. This is performed by pushing Keith needles along the edges of the bone through the nail. The trajectory of the needles should be aimed in a similar manner when passing through the bone as described above.
- The suture is then passed dorsally and tied over a nonadherent dressing and a tendon button after confirmation that the tendon is fully seating within the bone trough (**TECH FIG 2C,D**).
- Another option for repair is the use of bone anchors.
- If there is a large bone fragment on the tendon, this may be amendable to screw fixation into the distal phalanx.
- This repair can be augmented with a pull-through suture as well.

■ Zone II to V Repair

Tajima

- The Tajima modification of the Kessler uses two suture strands. If the proximal tendon is retracted into the palm, we will use a Tajima suture to draw the proximal tendon stump distally through the pulley system.
- The sutures are passed as they would for half of modified Kessler, but a separate suture is used on each side (**TECH FIG 3**).
- This technique is often applied when multiple tendons are injured. Sutures are passed into all of the injured tendons to allow tagging of proximal structures during exploration of the wound. Usually, once the bony structures are stabilized, the tendons are passed and then tied.

TECH FIG 3 • Tajima suture repair.

Modified Kessler

- The preparation of the zone 2 and 3 repairs may be complicated by the cruciate and pulley system blocking visualization, suturing, or passage. Generous windows should be made to allow the repaired site glide postoperatively.
- Align the proper orientation of the FDP and/or the FDS to prevent twisting and hold the proximal tendon in place with a 25-gauge needle.
- One or two slips of the FDS can be repaired at zone 2.
 - Some authors excise slips to maximize tendon gliding and minimize resistance. Some surgeons always repair the FDS with the rationale that if the FDP ruptures, the patient can preserve FDS function. Some excise the FDS to decrease tendon bulk in within the pulley system.
 - In our practice, we sometimes excise the ulnar slip of the FDS tendon depending on the tendon quality. We make this decision depending on the degree of tendon bulk and resistance after venting the pulleys.
 - The FDS is repaired using a horizontal mattress suture or a figure-of-8 suture using a 4-0 Ethibond or Tevdek suture.
- To start the modified Kessler technique, a suture is passed from the radial cut end of the tendon and exits out the volar surface 1 cm from the end.
- A transverse pass is then made from the radial side of the tendon transversely and out the ulnar side. This pass may be made closer to the cut

edge to lock the suture.

- Another loop is made passing the suture back into the volar aspect of the tendon and out the tendon end.
- The mirror image of the suture is passed on the other end and the knot is tied within the tendon ends (**TECH FIG 4**).
- A four-strand repair may be created with the addition of a second suture in the same pattern or with a horizontal mattress suture.

Locked Cruciate

- To begin the locked cruciate tendon suture, a 2-mm longitudinal slit is created 1 cm from the tendon edge and a suture is passed through this out the tendon end.
- The needle is then brought through the opposing tendon end and out 1 cm on the volar aspect.
- The suture is reinserted a few millimeters distal and lateral to the prior exit site and crossed through the tendon without locking.

TECH FIG 4 • Modified Kessler suture repair.

TECH FIG 5 • Locked cruciate suture repair.

- The suture is then reintroduced into the distal end and passed into other lateral edge across from the prior slit site.
- The needle is repassed retrograde a few millimeters distal to the insertion site and brought out the tendon end.
- This is passed into the opposing end again, looped back into the tendon a few millimeters distal, and crossed back into the distal tendon without locking.
- The needle exits the slit and the knot is tied within the tendon (**TECH FIG 5**).
- Slack should be removed from the suture and gapping approximated with each throw.

Modified Becker/Massachusetts General Hospital (MGH) Repair

- This is our preferred core suture technique when possible.
- The suture is introduced from the volar, radial of the tendon 1 cm from the cut end.
- Two epitendinous crisscross sutures are placed on each tendon end, tightened snugly, and the knot is tied on the outside of the tendon.
- A second suture passed in the same fashion is completed on the ulnar side of the tendon creating a four-core suture repair (**TECH FIG 6**).
- This repair can be completed with a single-armed suture, but a double-armed suture will allow safe passes to prevent accidentally catching the suture with subsequent passes during placement of the crisscross epitendinous sutures.
- A 5-0 or 6-0 monofilament epitendinous suture is often started dorsally prior to core suture completion. This may be placed after the core suture repair as well.
- The use of an epitendinous suture increases repair strength up to 20% and may improve tendon gliding.

TECH FIG 6 • Modified Becker/Massachusetts General Hospital (MGH) suture repair.

■ Epitendinous Repair: Running, Running Locking, and Silfverskiold Suture

- Running and running locking sutures are typically done with a monofilament 5-0 or 6-0 suture.
 - The epitendon is grasped with the suture, and a knot is tied approximating the ends. This end may be left free to tie too after completion of the suture technique as well.
 - The suture is then passed from superficial to deep on one end and then out deep to superficial on the other with advancement of each throw.
 - Either the suture is tied to the tail of the first throw or a new knot is created.
 - The running locking is completed in the same fashion, but locking loops are used instead.
- The Silfverskiold suture is analogous to a horizontal cross-stitch suture (**TECH FIG 7**).
 - It is performed by placing an anchor stitch and then taking 1- to 2-mm bites perpendicular to the axis of the tendon approximately 1 cm from the repair site. Tendon passes are always taken toward the surgeon.
 - The following suture pass is taken on the other side of the repair site, and the starting point is advanced away from the surgeon.
 - About 10 passes are needed to circumferentially encompass the tendon.
 - The epitendinous suture is then tied to the anchor suture.

TECH FIG 7 • A,B. Epitendinous repair with Silfverskiöld sutures.

PEARLS AND PITFALLS

Technique

- Use a Tajima suture to retrieve retracted tendons if needed. In the cases of combined injury, the suture is placed during the exploration/approach, the bone is fixed, and then the suture is passed and tied.
- Use a pediatric feeding tube or funnel to help pass sutures through the proximal pulleys.
- The primary goal of zone 2 tendon repairs is to repair the tendon with four-core sutures and an epitendinous suture.
- Use an epitendinous suture to increase repair strength. Consider placing the dorsal epitendinous suture before the core repair.
- Avoid traumatic handling of the tendon to prevent epitendinous injury that may lead to adhesion formation.
- The A4 pulley may be vented if the A2 pulley is competent.

Therapy

- In children, we prefer immobilization in a cast rather than an early motion protocol.
- If the tendon repair is strong, begin early motion protocols.
- If the tendon repair is tenuous, a less aggressive motion protocol is preferred. Adhesions can be addressed with tenolysis later.

POSTOPERATIVE CARE

- Passive digital flexion-extension results in loads of around 3 N.⁴
- Active digital flexion-extension results in loads of about 30 N.⁴
- Tendon excursion during passive digital flexion-extension ranges from 3 to 8

mm in vivo.⁵

- Hook and straight fist result in greater loads than does composite fist.⁶
- Wrist motion results in greater flexor tendon excursion.
- A postoperative dorsal blocking splint with wrist and digit flexion is applied. This splint is removed at the first postoperative visit and a thermoplastic or like dorsal blocking splint is fashioned to initiate therapy.
- Earlier protocols consisted of immobilization for at least 3 weeks. This resulted in loss of digit motion due to tendon scarring; therefore, newer protocols were established to allow excursion and prevent tendon adhesions
- Kleinert, Duran, and active place-and-hold are commonly employed early motion regimens. There are many modifications of these protocols as well.
- If we have high confidence in the repair, we will begin early motion using the pyramid protocol described by Groth.⁷
- If the repair is tenuous, we will use a modified Duran protocol.
- Overall, the choice of protocol is surgeon and case dependent.

OUTCOMES

- Chesney et al. reviewed multiple rehabilitation regimens for zone II flexor tendon injuries. No significant difference existed between early active and early passive protocols (Duran- and Kleinert-type protocols), and all protocols resulted with high rates of acceptable range of motion. Duran protocols had the lowest rate of ruptures during rehab (2.3%).⁸
- Starr et al. performed a systematic review of early active and early passive protocols for all zones of flexor tendon injury. They found that early passive range of motion protocols had a statistically significantly decreased risk for tendon rupture but an increased risk for postoperative decreased range of motion when compared to early active motion protocols.⁹

COMPLICATIONS

- Adhesions are the most common complication.
- Tendon rupture may occur when loading during rehabilitation exceeds the strength of the repair and the healing tendon. It is sometimes not possible to distinguish between tendon rupture and adhesions if the proximal tendon stump scars to the FDS and the proximal phalanx.
- Quadriga occurs when the FDP is shortened. Because the FDP has a common muscle belly, once the finger with the shortened FDP has fully flexed, the other

fingers cannot flex any further.

Repair of Multiple Flexor Tendon Injury at Wrist Zone V (Spaghetti Wrist)

38

CHAPTER

Jacques A. Machol IV, Neal Chen, and Kyle R. Eberlin

DEFINITION

- Volar wrist trauma with tendon, nerve, and arterial injuries is often referred to as a “spaghetti wrist.”
- Specific criteria for the definition of a “spaghetti wrist” vary in the literature, with some authors defining it as injury to at least three of the volar wrist structures including at least one nerve,^{1,2} with others defining this injury as inclusive of both median and ulnar nerve injuries at the level of the wrist.³
- Other authors have defined this injury as involving a minimum of 10 structures in the wrist.

ANATOMY

- The volar wrist structures include the radial and ulnar arteries, the median and ulnar nerves (along with the palmar cutaneous branch and the dorsal ulnar sensory branch), the flexor pollicis longus (FPL), the four flexor digitorum superficialis (FDS) tendons, the four flexor digitorum profundus (FDP) tendons, the palmaris longus (PL), the flexor carpi ulnaris (FCU), and the flexor carpi radialis (FCR) tendons. Any or all of these structures can be injured with a volar wrist laceration (**FIG 1**).
- The superficial nature of these structures and thin cutaneous coverage render them highly susceptible to penetrating injuries.
- At the wrist, the FDS tendons to the long finger (LF) and ring finger (RF) are volar to the FDS tendons to the index finger (IF) and small finger (SF).
- The FCU is volar to the ulnar artery and ulnar nerve. The ulnar artery is typically superficial (volar) to the ulnar nerve; it is therefore possible to injure

the FCU and ulnar artery while sparing the ulnar nerve.

- The palmar cutaneous nerve is often injured.
- Flexor tendon injuries in the spaghetti wrist are in zone V (see Flexor Tendon chapter for details)

PATHOGENESIS

- These injuries are often self-inflicted but also may result from other traumatic causes.⁴
- They often are the result of sharp lacerations but can also be caused by crush injuries.
- The mechanism of injury is most often sharp glass lacerations, followed by knife wounds and saw injuries.
- The median nerve and FDS tendons are the most commonly injured structures, because they are located superficially and centrally in the volar wrist.
- These injuries are more common in males.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A focused history and physical examination is performed with emphasis on the etiology and mechanism of injury, sensory and vascular examination, and examination of each individual tendon in the volar wrist.
- Self-inflicted spaghetti wrist injuries should ideally be identified prior to surgery. Psychiatry consultation is helpful for management.
- A thorough vascular examination should be performed including inspection for color and capillary refill, a Doppler exam with Allen test, and pulse oximetry of the digits.
- A formal nerve examination, including evaluation for light touch and two-point discrimination, intrinsic motor function, and palmar abduction, should be performed.
- The surgeon can glean much information about the status of tendon injuries simply by observing the digital cascade at rest, as the attitude of the digits can reflect the presence or absence of intact tendons.
- In these cases, tenodesis testing is not possible usually because the wrist cannot be flexed or extended because of the injury.

IMAGING

- Plain film radiographs are obtained to assess for fracture and foreign body.

SURGICAL MANAGEMENT

- Early definitive surgical management is recommended, particularly in cases of vascular or nerve injuries.
- Thorough debridement and removal of foreign material with copious irrigation is paramount.
- Identification and labeling of all injured structures is performed; a checklist is helpful to organize one's approach and ensure repair of all injured structures.
- It is important to label the proximal tendons, as the orientation is clear prior to dissection and may be lost with mobilization. The distal tendon ends are easily identified by manual traction intraoperatively.
- The deep structures including the FDP and FPL are repaired first, unless the hand is dysvascular in which case an arterial repair shunting is performed first (usually the radial artery).
- It is important to repair injured structures in a manner that facilitates microsurgical repair of the nerves and/or arteries.

FIG 1 • Distal wrist axial slice anatomy. Flexor carpi radialis (FCR), palmaris longus (PL), flexor digitorum superficialis (FDS), flexor digitorum profundus (FDP), index finger (IF), long finger (LF), ring finger (RF), small finger (SF), and flexor carpi ulnaris (FCU).

- It is important to identify injured structures, repair deep structures, and then progress to more superficial structures.
- If microsurgical repair is anticipated, superficial structures such as the FCR and FCU are repaired last.

Preoperative Planning

- The aforementioned thorough preoperative examination formulates a concrete, definitive operative plan.
- The surgeon and patient should be prepared for vein and/or nerve grafts, depending on the time elapsed and mechanism of injury.

Positioning

- The patient is positioned supine with the arm abducted on a hand table; a tourniquet is used.
- The ipsilateral lower extremity is prepped sterilely for vein or nerve graft(s), if needed.
- The entire forearm to just above the elbow is prepped. This is particularly germane with distal lacerations near the wrist crease, where the distal tendon ends may retract into the carpal tunnel.
- Skin flaps can be retracted with either elastics/hooks or retraction sutures.

TECHNIQUES

■ Exposure

- The existing wound is extended proximally and distally to provide access to injured structures.
 - Do not try to limit incisions in these cases. Wide exposure is preferred (**TECH FIG 1**).
- Proximally, the incision is extended in linear, longitudinal fashion often in the central aspect of the volar forearm.
- Distally, an extended carpal tunnel incision may aid in mobilization of tendons for repair and is frequently performed to release of the transverse carpal ligament in anticipation of postoperative swelling.

TECH FIG 1 • **A.** Initial wound presentation with exposed injuries. **B.** Extension of the existing wound proximally and distally to provide access to injured structures.

■ Exploration and Tagging of the Structures

- The proximal tendons are exposed and tagged with one-half of the preferred suture technique and labeled (**TECH FIG 2A**). A four-core strand suture technique is commonly used.
- Arteries and nerve are tagged with a small monofilament suture with long tails.
- A checklist is used to ensure repair of all structures (**TECH FIG 2B**).

TECH FIG 2 • **A.** Tagging of the proximal structures to ensure proper anatomical repairs. **B.** Checklist ensuring repair of all structures.

■ Repair of Injured Structures

- Tendons are repaired first from deep to superficial, and often from radial to ulnar under tourniquet.
- The choice of tendon repair varies based on surgeon preference and experience but should entail at least four core strands.
 - We prefer a modified Becker, ie, MGH repair for flexor tendons in zone V. Epitendinous repair is not needed because gliding is not impeded in zone V and the surgeon needs to expedite the repairs because of the numerous structures injured.
- Microsurgical repair of the nerves and arteries is then performed.
- The tourniquet can be deflated to visualize arterial inflow and endoneurial bleeding during neurorrhaphy (**TECH FIG 3**).
- Meticulous nerve repair is critical; this should be performed by the most senior surgeon involved in the operation.
 - Care should be taken to avoid fascicular overlap during tension-free neurorrhaphy.
- If there is a single arterial injury, we tend to perform vascular repair even with a perfused hand.
 - We occlude the other major artery for 5 minutes at the time of reperfusion (for instance, the radial artery following ulnar artery repair) to allow for antegrade flow into the hand through the fresh vascular anastomosis.

TECH FIG 3 • Status post microsurgical repair.

PEARLS AND PITFALLS

Technique

- Careful preoperative examination helps surgical planning.
- Identification and tagging of proximal tendons will ensure correct repair of structures; a surgical checklist is helpful.
- Atraumatic tendon and tissue handling will facilitate gliding of tendons postoperatively.
- Meticulous epineurial repair following adequate nerve debridement will optimize chances of neural recovery; care should be taken to avoid fascicular overlap.
- Have the contralateral leg prepped if nerve grafts or vein grafts are anticipated.

Physical exam

- An Allen test and thorough nerve exam should be performed preoperatively.
- Inspection of the digits can often reveal the extent of tendon injuries.

Therapy

- Dedicated occupational/hand therapy is required postoperatively; this will depend on the strength of repair and the patient's motivation and compliance with postoperative instructions.
- Patients with self-inflicted lacerations may require a longer period of immobilization, sometimes involving casting.

FIG 2 • Eight months (A,B) and 2 years (C,D) postoperatively.

POSTOPERATIVE CARE

- Patients are placed in a dorsal blocking “clam digger” splint with the wrist in 20 degrees of flexion, MP joints at 90 degrees of flexion, and PIP/DIP joints with mild flexion to off-load the tendon, nerve, and arterial repairs. The splint should extend to the fingertips.
- Strict elevation and non-weight bearing is emphasized, particularly for patients with self-inflicted lacerations.
- Continuous pulse oximetry is utilized for patients presenting with both radial and ulnar artery injuries or dysvascular hands; aspirin is utilized for 1 month postoperatively.
- The specific regimen of postoperative hand therapy is based on the quality of the repairs and the compliance of the patient; we prefer early active motion protocols for sophisticated patients who understand the nature of their injury and 3 to 4 weeks of immobilization for patients with self-inflicted injuries who

are unwilling or unable to follow strict postoperative instructions.

OUTCOMES

- Functional outcomes depend on the overall severity of injury and number of injured structures but are often predicated upon the degree of neural recovery (**FIG 2**).
- With sharp injuries, more than 50% of patients will recover protective sensation, but intrinsic dysfunction is common with ulnar nerve injuries.
- Digital range of motion and strength can be satisfactory, particularly with early active motion protocols in compliant patients.⁴
- Patients can be expected to have some degree of dysfunction compared to their premorbid state.

COMPLICATIONS

- Tendon adhesions and/or stiffness, greatest when patients are immobilized for extended periods of time postoperatively
- Tendon rupture, greatest when patients are not compliant with splinting or therapy instructions
- Infection and delayed wound healing, greatest with contaminated wounds
- Pain resulting from neuroma
- Clawing and intrinsic minus hand secondary to poor ulnar nerve recovery
- Arterial insufficiency or cold intolerance

39 Staged Flexor Tendon Grafting and Pulley Reconstruction

CHAPTER

Richard Tosti, Jacques A. Machol IV, and Neal Chen

DEFINITION

- Flexor tendon reconstruction refers to the restoration of the flexor mechanism through the use of tendon grafts.
- Pulley reconstruction is the recreation of the flexor tendon sheath in order to prevent bowstringing and optimize strength.

ANATOMY

- Nine flexor tendons originate in the forearm. Flexor pollicis longus inserts at the base of the distal phalanx of the thumb. Four flexor digitorum superficialis (FDS) and four flexor digitorum profundus (FDP) tendons insert on the volar base of the middle and distal phalanges, respectively.
- The FDS tendons are superficial to the FDP in the hand, but as they enter the fibrous sheath, the FDS bifurcates into two slips, which are directed dorsally to their insertion.
- The flexor tendon sheath is a fibrous tunnel through which the flexor tendons glide. Composed of annular and cruciate pulleys, the sheath prevents bowstringing, reduces the flexor moment arm (imparting strength and efficient excursion), and provides nutrition (**FIG 1**). The thumb flexor sheath is composed of annular and oblique pulleys.
- The flexor sheath extends from the metacarpal head to the distal phalanx.

FIG 1 • Flexor tendon sheath of a finger consisting of annular and cruciate pulleys.

PATHOGENESIS

- Acute flexor tendon rupture occurs as a result of trauma, including laceration, avulsion, crush, or burn.
- Attritional ruptures may also occur from synovitis, Mannerfelt syndrome, prominent implants, bony prominences, infections, and neoplasms.

NATURAL HISTORY

- Following a rupture, the proximal end of the tendon retracts, leaving an empty space within the sheath.
- In as early as 3 to 6 weeks, irreversible contracture of the muscle tendon unit, degeneration, and scarring within the flexor sheath may occur. The tendon sheath volume will shrink without an intact tendon, which limits passage of tendons through the sheath after tendon repair.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients lose the ability to flex the finger at the proximal interphalangeal (PIP) joint or distal interphalangeal joint (DIP) when the FDS or FDP tendons are disrupted.
- Often the cascade of the hand is altered. The affected digit assumes a more extended posture.
- A skin injury overlies the approximate level of tendon injury
- “Tenodesis” effect of the hand is lost. When the wrist is passively extended, the affected finger does not flex.
- Active motion is lost. FDS rupture is detected by observing loss of PIP flexion in the affected digit while holding the adjacent digits in extension. Extending the adjacent digits isolates the FDS because the FDP tendon of the affected digit is placed at a mechanical disadvantage due to the common origin. FDP rupture is detected by stabilizing the PIP in extension and observing a lack of active flexion at the DIP joint.
- “Tenodesis” testing can also help detect flexor tendon injuries. When the wrist is extended, the digits should flex reciprocally if the flexor tendons are intact. If the flexor tendon is lacerated, there will be lack of reciprocal flexion in the injured digits.

IMAGING

- Flexor tendon rupture is usually diagnosed by history and physical exam.
- Radiographs may be helpful to evaluate for avulsion injuries or bony prominences causing attritional rupture.
- Computed tomography may also be useful in evaluating for carpal bone spurs in suspected attritional ruptures.
- Ultrasound or magnetic resonance imaging may be useful in determining the level of proximal tendon retraction.

DIFFERENTIAL DIAGNOSIS

- Adhesions. It is difficult to distinguish between adhesion and rupture clinically.
- Intra-articular injury
- Nerve injury
- Neuromuscular disorders

NONOPERATIVE MANAGEMENT

- Elderly, low-demand patients with comorbidities may not have an outcome worth the overall risk for multiple reconstructive procedures. Additionally, these patients may not be able to complete a rigorous postoperative protocol.
- Physical rehabilitation to maximize passive joint motion is critical prior to tendon reconstruction procedures.
- Although not considered “nonoperative,” alternative procedures to reconstruction include joint fusion or digit amputation, which could be considered for patients with injuries to multiple structures within the digit.
- Patients with an intact FDS may have reasonable function even if the FDP has been lacerated. In these situations, no reconstruction is reasonable. If the DIP is unstable, fusion is an option, but in many cases, this is not necessary.

SURGICAL MANAGEMENT

- Direct tendon repair should be performed when possible.
- Single stage tendon grafting can be performed for acute segmental tendon defects or delayed injuries without excessive retraction and good passive motion. An intact flexor tendon sheath is required.
- Two-stage flexor tendon reconstruction is indicated for failed direct repairs in zone II, severe injuries with concomitant injury to the adjacent bone or joint, chronic injuries with excessive scarring, or loss of flexor sheath.
 - Two-stage reconstruction was developed because joint contracture, flexor sheath volume/pulley insufficiency, and tendon length were problems. Two-stage reconstruction allows the surgeon to address these factors prior to addressing the tendon.
 - Prior to the first stage, wound healing, and joint contracture are addressed. The first stage allows for reconstitution of the flexor sheath and pulley reconstruction.
 - Once a gliding space is established, the second stage of the reconstruction can be performed with minimal scarring and inflammation.
- If the tendon is too short, patients will have problems with quadriga, ie, the tendon excursion for the injured finger would be shorter than the other digits. When the injured finger was fully flexed, the other fingers would not flex completely because of the common FDP muscle belly.
- If the tendon was too long, some patients developed a lumbrical plus finger. As the FDP contracts, the lumbricals tighten, resulting in paradoxical extension of the PIP joint through the lateral bands.
- Flexor tendon reconstruction, although not a perfect solution, is a method that

has more consistent results than these other techniques.

Preoperative Planning

- If autograft is planned for the procedure, one should ensure the presence and integrity of the tendon. Many options are possible, but the most common are palmaris longus, plantaris, and digital long toe extensors of the second, third, or fourth toes. Allograft tendon is also an option.
- Plan for a small-caliber graft (4–5 mm diameter).
- Plan for only one graft.
- Do not sacrifice FDS if it is found intact.
- Perform the repairs outside of the tendon sheath.
- Repair the proximal juncture to the FDP tendon to power the graft.

Positioning

- Position the patient supine on a hand table with a nonsterile upper arm tourniquet.

Approach

- A volar Bruner-style incision is planned along the length of the finger.
- A separate zigzag incision in the palm or distal forearm may be needed as well.

TECHNIQUES

■ Single-Stage Tendon Grafting

- The tendon sheath is approached through a volar Bruner incision (**TECH FIG 1A**) and must be examined for competency particularly for the A2 and A4 pulleys.
 - If an inadequate sheath is found, a staged reconstruction should be performed.
 - If single-stage reconstruction with tendon graft is planned, all the finger joints must have full supple motion and the skin over the tendon sheath must be soft so that the finger can move smoothly during therapy.
- The sheath should be preserved as much as possible.

- Leave FDS intact if it is not disrupted. The graft can be passed anatomically through the decussation.
- Often, both FDS and FDP are disrupted.
- The insertion of FDS can be left with a 1- to 2-cm tail to provide a gliding surface.
- The proximal FDS is transected under traction and allowed to retract (**TECH FIG 1B,C**).
- The FDP insertion is similarly left with a 1- to 2-cm stump. If no FDP stump is available, the graft can be inserted directly into the bone.
- The proximal FDP is often prepared in the palm if no scarring is present but can also be prepared in the distal forearm.
- When in the palm, the FDP is “freshened” with a blade just distal to the lumbrical origin. The proximal tendon graft is woven to the FDP at the level of the lumbrical muscle takeoff to assure that the proper tension can be set to avoid a lumbrical plus finger in which premature contraction of the lumbrical causes PIP joint extension when attempting finger flexion.

TECH FIG 1 • Single-stage flexor tendon reconstruction. **A.** Bruner incisions in the digit and palm. If needed, a forearm incision is marked for more proximal rod placement. **B,C.** The proximal tendon is excised. **D.** The tendon sheath is intact. **E,F.** The tendon graft is passed through the distal phalanx and tied over a button. **G.** The tendon suture is weaved to the profundus tendon proximally with fingers in slight flexion. **H.** Completed single-stage tendon

reconstruction.

- The lumbrical may be released if it is scarred.
- At this point, a moist gauze is placed over the wound, and the graft is harvested.
- The harvested graft may be first secured to the distal or proximal junction first, but we prefer to secure it first distally to facilitate setting tension.
- The graft is sutured. We prefer a smooth 2.0 Prolene or a 4.0 steel wire in a horizontal mattress configuration to facilitate easy pullout.
- The sutures are shuttled through the tendon sheath by using a tendon passer (**TECH FIG 1D**). The ends of the suture are brought distally and can be used to slide the tendon graft through the sheath.
- The distal end of the graft is woven once through the FDP stump with the tendon weaver (**TECH FIG 1E,F**).
- A Keith needle is placed into a wire driver and drill across the base of the distal phalanx.
- One suture end is threaded through the eyelet and passed dorsally through the nail plate either through or around the bone, taking care not to pierce the germinal matrix. The other suture is passed the same way.
- The sutures may be tied over a polypropylene button or over the nail plate.
- Alternatively, the graft can be secured with a small suture anchor in the distal phalanx; the anchor is placed in the FDP insertion and angled slightly proximally with care to avoid intra-articular penetration of the DIP joint.
- The graft is then sutured to the distal FDP stump at the distal weave.
- The wrist is positioned in neutral, and the graft is tensioned to place the finger in slight flexion and aligned with the natural cascade (**TECH FIG 1G**). Err on the side of overtensioning rather than undertensioning.
- The proximal end of the graft is then weaved through the proximal FDP tendon at the correct tension (**TECH FIG 1H**).
- We prefer three weaves, each 90 degrees to each other, which are secured with figure-of-8 sutures.

■ Two-Stage Flexor Tendon Reconstruction

Stage 1

- Approach the finger with a volar Bruner incision (**TECH FIG 2A**).
- Assess the flexor sheath and preserve as much as possible.
- If the sheath is deficient, pulley reconstruction is indicated.
- A lacerated sheath may be repaired in this stage as long as it does not hinder the gliding of the rod.
- A stenotic sheath may require dilatation or partial release in order to pass the rod.
- Cut the FDS and FDP leaving a 1- to 2-cm stump at the insertion sites. The excised tendon can be used for pulley reconstruction and should be maintained on the field during the case.
- There are two approaches to rod placement, depending on the anticipated location of the tenorrhaphy. Some surgeons perform the tenorrhaphy in the palm, whereas others perform the tenorrhaphy at the level of the forearm.
 - If there is a large amount of scarring in the palm, forearm placement is preferred.
 - If a forearm tenorrhaphy is used, a palmaris longus tendon is usually too short and a plantaris tendon or other longer tendon may be needed at the secondary reconstruction.
- An incision can be made in the palm or in the distal forearm.
- Identify the FDS and FDP tendons by using a turn-key motion with an Allis clamp. This is performed by clamping around the tendon and then twisting the clamp so the tendon wraps around the tines. This allows the surgeon to apply a force in line with the tendon and helps avoid pulley rupture.
- The FDS is released and allowed to retract proximally in most cases, but may be retained as the motor for the second stage if the FDP is of poor quality.
- Shorten the FDP but tag it with a suture and sew it side to side to an adjacent FDP tendon to prevent retraction and allow easy identification in stage 2.
- Suture the silicone rod into the distal FDP stump. The size of the rod should fit snugly into the sheath. It is usually 4 to 6 mm.
- Guide the rod through the flexor sheath (**TECH FIG 2B–D**) and allow it to float freely through the carpal tunnel and into the forearm.
- You should observe the rod in the proximal forearm incision, and it should glide smoothly without buckling as the finger is taken through a range of motion.
- Alternatively, the silicone rod can be loosely tacked to the FDP at the level

of the palm if it has not retracted proximally.

- Over the course of 2 or 3 months, the gliding silicone rod creates a lubricated pseudosheath.¹

Stage 2

- Use the previous incisions to identify the silicone rod proximally and distally.
- Obtain the tendon graft. Be sure the length of the graft will be sufficient to span the length of the defect (**TECH FIG 3A,B**).

TECH FIG 2 • Stage 1 of two-stage flexor tendon reconstruction. **A.** Volar Bruner incision in the finger and palm. **B.** The Hunter rod placement in flexor sheath. **C.** Hunter rod sutured to the FDP stump. **D.** Completed stage 1 of two-stage tendon reconstruction.

- Identify the rod distally in the finger.
- Cut the sutures between the rod and the FDP stump and suture the distal end of the rod to the proximal end of the graft (**TECH FIG 3C**).
- Pull the rod through the proximal incision, which will shuttle the graft

through the sheath.

- Perform a tendon weave on the distal FDP stump as described above for single-stage grafting. If no stump is present, the graft can be inserted into the distal phalanx with transosseous sutures tied over a button or the nail plate or with a suture anchor (**TECH FIG 3D**).
- Estimate the tension of the graft to produce slight flexion aligned with the natural cascade (**TECH FIG 3E**).
- Err on the side of overtensioning rather than undertensioning.
- Perform a Pulvertaft weave on the proximal FDP using three orthogonal weaves (**TECH FIG 3F**).
- If the proximal FDP stump cannot be identified, a tenodesis to the adjacent FDP tendon can be performed.

TECH FIG 3 • Stage 2. **A,B.** The tendon graft is harvested. **C.** The sutures are cut between the rod and the FDP stump, and the distal end of the rod is sutured to the proximal end of the graft. **D.** A tendon weave is performed on the distal FDP stump. **E.** The tension of the graft is estimated to produce slight flexion aligned with the natural cascade. **F.** Completed stage 2 of two-stage tendon reconstruction.

■ Paneva-Holevich Modification

- Described in 1969, this modification obviates the need for tendon graft harvest in stage 2.²
- In stage 1, the volar finger is approached and the silicone rod is secured to the distal FDP or the distal phalanx as described above.
 - The FDS and FDP tendons are both identified in the palm and transected at the level of the lumbrical origin proximal to the A1 pulley. Both distal ends are sutured to each other using a locking core suture technique. We prefer a Kessler stitch with a running epitendinous stitch.
 - The FDP-FDS “loop” will heal over 3 months.
- In stage 2, the finger is exposed again.

- The FDS tendon is transected as far proximal as possible. Pull the FDS-FDP loop out of the palm. The proximally cut FDS tendon now becomes the distal end of the graft.
 - Suture the distal end of the tendon graft to the silicone rod and shuttle the graft through the pseudosheath.
 - Tension the graft and secure it as described above.
-

■ Pulley Reconstruction

- Pulley reconstruction is performed at the first stage of the tendon reconstruction if the A2 and A4 pulleys are deficient (**TECH FIG 4A**).
- We prefer the tendon-wrapping method described by Bunnell.³
- Approximately 12 cm of graft may be required to encircle the phalanx twice. Oftentimes this can be obtained from excised flexor tendon.
- The A2 and A4 pulleys should be reconstructed.
- At the level of the proximal phalanx, the graft lies deep to the extensor mechanism and deep to the neurovascular bundle, so that the intrinsic tendons and the finger vascularity are not disrupted.
- Whipstitch one end of the graft with a 4.0 braided suture.
- Use a curved hemostat to dissect around the proximal phalanx deep to the extensor mechanism, and pass the suture into the clamp.
- Pass the graft around the mid shaft of the proximal phalanx twice and suture to itself using 3.0 nonabsorbable suture.
- At the level of the middle phalanx, the graft is passed superficial to the extensor mechanism but still deep to the neurovascular bundle. Encircle the middle phalanx twice and suture the graft to itself (**TECH FIG 4B–D**).
- An alternative method is to shoestring the graft through existing pulley edges. The residual pulley is often stiff enough to support the weave.

TECH FIG 4 • Pulley reconstruction using tendon autograft. **A.** A2 and A4 pulley location. **B.** The grafts are looped twice around the proximal phalanx. **C,D.** The graft is passed under the extensor mechanism for the A2 reconstruction and over the extensor mechanism for the A4 reconstruction.

PEARLS AND PITFALLS

Indications

- Single-stage grafting is indicated for a segmental gap in the tendon with an intact sheath.
- Two-stage grafting is indicated for a segmental tendon gap with excessive scarring, multistructure injury, failed tendon zone II repair, and/or a deficient sheath.
- Digits considered for reconstruction should have adequate

	vascularity and protective sensation. ■ Alternatives to tendon reconstruction include adjacent FDS to FDP tendon transfer, arthrodesis, and amputation.
Graft planning	■ Be sure the desired graft is anatomically present. ■ Plan for a graft with sufficient length. ■ If the graft needs to reach the palm, a palmaris graft may be sufficient. ■ If the graft needs to reach the forearm, a plantaris graft may be necessary. ■ If a graft is not present, an allograft gracilis or semitendinosus is an acceptable alternative. ■ The graft should be about 4–5 mm in width to pass through the sheath easily.
Preservation of intact structures	■ Do not sacrifice an intact FDS to pass a tendon graft. ■ Preserve as much of the native sheath as possible—not just A2 and A4.

POSTOPERATIVE CARE

Stage 1

- The major goal of stage 1 is to maintain passive range of motion
- 0 to 2 weeks: edema control, dorsal thermoplast splint (wrist neutral, MP joint 60 degrees of flexion, IP joints 0 degrees). Passive flexion and active/passive extension for all joints 6 times per day. If a pulley reconstruction was performed, a thermoplast circumferential pulley ring is worn for 6 weeks.
- 2 to 6 weeks: Remove splint. Buddy strap affected finger to adjacent finger. Continue active and passive exercises until stage 2 is performed (approximately 12 weeks).

Stage 2 (Modified Duran)

- 0 to 3 weeks: Edema control, dorsal thermoplast splint (wrist 20 degrees of flexion, MP joint 60 degrees of flexion, IP joints 0 degrees). Passive flexion and active/passive extension for all joints 6 times per day.
- 3 to 4 weeks: Add active range of motion (AROM), tendon gliding, and place hold exercises in the splint.
- 4 to 6 weeks: Exercises can be performed out of splint. Add blocking exercises to PIP and DIP. Add wrist tenodesis exercises. Add grasp, dexterity, and ADL

exercises.

- 6 to 8 weeks: Splint is only worn at night and in crowds. Volar pancake or IP joint extension splints may be added if necessary. Add light resistance exercises.
- 8 to 12 weeks: Discontinue splint. Add progressive resistance exercises and work simulation activities.

OUTCOMES

- Outcomes results are graded by a variety of measures including total active arc of motion (TAM), grip and pinch strength, and scoring systems by Schneider, Stark, and Strickland.⁴⁻⁶
- In general, results of primary repair are superior to reconstruction, and fingers with an intact FDS obtain better motion than do those without one.⁷ Other factors that portend a better prognosis are younger patient, less soft tissue scar, good preoperative mobility, and at least one intact sensory nerve.⁸
- Grafting through an intact FDS, Stark et al. reported “satisfactory” finger flexion in 20 of 25 patients, defined as a distance of the pulp to distal flexion crease within 3.2 cm and 20-degree active DIP flexion.⁵ Using similar criteria, McClinton et al. reported success in 87 of 100 patients with an average of 48 degrees of DIP flexion.⁹
- Two-stage grafting reported by Hunter and Salisbury resulted in pulp to crease flexion within 3.2 cm in 85% of the 69 cases.¹⁰
- TAM for two-stage grafting ranges from 186 to 206 degrees.^{7,11,12}

COMPLICATIONS

- Adhesion of the graft is the most common complication. A tenolysis may be required 3 to 6 months after stage 2 reconstruction.
- Bowstringing, tendon rupture, and infection are also not uncommon complications.
- A tight FDP graft may cause the “quadrigea effect,” whereby the adjacent digits experience a flexor lag as described earlier.
- A loose FDP graft may cause imbalance in the finger. A swan-neck deformity or a lumbrical plus finger may be the result. Lumbrical plus finger is diagnosed when “paradoxical extension” of the IP joints occurs when the patient attempts to make a fist; the lumbrical originates on the FDP and pulls the IP joints into extension when a retracted FDP contracts. Retensioning the graft or resection of the lumbrical origin may be required.

CHAPTER Tenolysis of Flexor Tendons

Richard Tosti, Jacques A. Machol IV, and Neal Chen

DEFINITION

- Total active arc of motion in the fingers is approximately 260 degrees, which is the sum of each individual joint: metacarpophalangeal (MP) joint 85 degrees, proximal interphalangeal (PIP) 110 degrees, and distal interphalangeal (DIP) 65 degrees.
- Flexion contracture is a loss of passive extension. Extension contracture is a loss of passive flexion.
- Flexion lag is a loss of active flexion, but preserved passive flexion. Extension lag is a loss of active extension, but preserved passive extension.
- This chapter will primarily focus on loss of digital motion caused by adhesions of the flexor tendon.

ANATOMY

- The strength and versatility of the hand is dependent upon the balance and gliding of the long flexors and extensors and the intrinsic muscles.
- The extensor apparatus is composed of four lumbrical muscles, four dorsal interossei, three volar interossei, four extensor digitorum communis (EDC) tendons, the extensor indicis proprius (EIP), and the extensor digiti quinti (EDQ).
- The long extensors (EDC, EIP, EDQ) originate in the forearm and insert on the base of their respective proximal phalanx via the sagittal band attachments to the volar plate. The long extensors continue distally to insert on the base of the middle phalanx as the central slip but also give two “lateral slips” that join the intrinsic tendons to form the lateral bands, which insert on the base of the distal phalanx as the terminal tendon.

- The intrinsic muscles originate in the hand and insert on the extensor apparatus. The transverse fibers of the extensor hood link the intrinsic tendon and the proximal phalanx. The oblique fibers of the extensor hood link the intrinsic tendon and the middle phalanx. The tendons of the intrinsic muscles join the lateral slips of the long extensor to form the lateral bands, which insert as the terminal tendon.
- Important to note is the course of the intrinsic tendon relative to centers of rotation at the finger joints. At the MP joint, they course volar to the axis of rotation producing a flexion moment. At the PIP and DIP joints, they course dorsal to the axis of rotation producing an extension moment.¹
- Nine flexor tendons originate in the forearm. Flexor pollicis longus inserts at the base of the distal phalanx of the thumb. Four flexor digitorum superficialis (FDS) and four flexor digitorum profundus (FDP) tendons insert on the volar base of the middle and distal phalanges, respectively.
- The FDS tendons are superficial to the FDP in the hand, but as they enter the fibrous sheath, the FDS bifurcates into two slips, which are directed dorsally to their insertion.

PATHOGENESIS

- Traumatic or postsurgical stiffness usually begins with edema or hematoma.²
- The fluid distends the joints and surrounding structures, becoming a physical barrier to motion.
- The cellular response to injury initiates the inflammatory cascade.
- The inflammatory cascade leads to fibroblast accumulation and fibroblast proliferation into myofibroblasts.
- Reaction to foreign material such as metal plates stimulates adhesion formation as well.
- Persistent motion loss leads to soft tissue contracture.

NATURAL HISTORY

- Contracture or adhesions of dorsal structures generally limit passive flexion. These structures include the dorsal skin, extensor tendons, intrinsic tendons, dorsal capsule, and collateral ligaments.
- Contracture or adhesions of the flexor tendons generally limit active flexion.
- Contracture or adhesions of the volar structures limit passive extension. These structures include the volar skin, flexor tendons, and volar capsule.
- Contracture or adhesions of the extensor tendons limit active extension.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The most common stiff posturing is MP joint extension and IP joint flexion. The MP joint is a cam shape, which holds the greatest fluid volume when in extension. Extension at the MP creates a relative tension on the flexor tendons that brings the IP joints into flexion.
- However, a variety of postures and motion limitations are seen (Table 1).

Table 1 Assessment of a Stiff Finger

Cause	Active Extension	Passive Extension	Active Flexion	Passive Flexion
Extensor tendon adhesion	–	+	–	+/-
Dorsal skin or capsular contracture	+	+	–	–
Flexor tendon adhesion	–	+/-	–	+
Volar skin or capsular contracture	–	–	+	+
Dorsal and volar combined ^a	–	–	–	–
Intrinsic contracture ^b	+	+	–	–

^aCombined pathology of dorsal and volar structures by adhesion and/or contracture.

^bTesting of PIP joint with the MP joint extended.

- Begin with assessment of passive and active range of motion (AROM).
- Passive motion greater than active motion suggests a barrier outside the joint (adhesion, rupture, denervation).
- Passive motion of the PIP joint that varies with the position of the MP joint suggests a barrier outside the joint (intrinsic or extrinsic tightness).
- Passive motion barriers may occur from pathology either within the joint or outside the joint.
- Passive motion barriers mask active motion (ability or disability); thus active joint motion can only be assessed after correction of passive motion barrier.

IMAGING

- Stiffness is usually diagnosed by history and physical exam.
- Radiographs may be helpful to rule out bone or joint malalignment as a cause.

DIFFERENTIAL DIAGNOSIS

- Tendon rupture
- Joint contracture

NONOPERATIVE MANAGEMENT

- Prior to any attempt at tenolysis, tissue homeostasis must be achieved. This includes a stable, supple soft tissue envelope, durable bony stability, and edema control.
- It is preferable to gain passive range of motion before a tenolysis procedure if possible.
- Daytime dynamic splints and nighttime static splints can help regain motion. Dynamic splints are typically not worn at night, as they may lose their position.
- Progressive static splints or serial casting can also be successful.

SURGICAL MANAGEMENT

- Surgery may be considered for disability resulting from stiffness if 6 months of nonsurgical management has failed to resolve symptoms.

Preoperative Planning

- Wide-awake surgery under local anesthesia has the advantage of assessing gains in active motion so that intraoperative modifications can be made.
- Hardware removal may be required but should only be performed after bony union has occurred.
- A flexion contracture may be caused by any combination of volar skin contracture, flexor tendon adhesion, or volar capsular contracture; these structures can be addressed by Z-plasty lengthening, flexor tenolysis, or joint release, respectively. Only after the flexion contracture is released can the integrity of the extensor mechanism be assessed.³
- An extension contracture may be caused by dorsal skin contracture, extensor tendon adhesion, or dorsal capsule; these structures can be addressed by Z-plasty lengthening, extensor tenolysis, or dorsal capsulotomy/collateral ligament release, respectively. Only after the extension contracture is released can the integrity of the flexor tendons be assessed.³

- A flexion lag is often caused by adhesions between the flexor tendon and surrounding bone, soft tissue, and skin. It may only be discovered after release of an extension contracture.
- An extension lag is often caused by adhesions between the extensor tendon and surrounding bone, soft tissue, and skin. It may only be discovered after release of a flexion contracture.

Positioning

- Position the patient supine with the arm on a hand table.
- A nonsterile tourniquet may be used proximally.

Approach

- Dorsal approach to the finger for extensor tenolysis is made through either a longitudinal incision centered over the PIP joint or a radially based curvilinear incision.
- For flexor tenolysis, a volar Bruner incision is the most common approach, although a longitudinal midaxial incision can be considered.
- In patients with a skin contracture, Z-plasty is often helpful.

TECHNIQUES

■ Extensor Tenolysis With or Without Dorsal Capsular Release

- The extensor mechanism is exposed, and any adhesions to the skin are released.
- A Freer elevator can be used to free the extensor hood from the proximal phalanx. This is usually performed from proximally to distally or from laterally to centrally under the lateral bands.
- Caution is taken to avoid detaching the central slip.
- Adhesions to the middle phalanx can also be released from under the lateral bands/extensor hood.
- If there is a PIP joint contracture present, the collateral ligaments can be excised from underneath the lateral bands.
- Adhesions at the level of the metacarpal are approached in a similar manner

(**TECH FIG 1**).

- Hardware, if present, should be removed at the time of tenolysis.

TECH FIG 1 • Extensor tendon adhesions after fixation of metacarpal fracture, dorsal approach showing adhesions of the extensor tendon to the skin and underlying plate.

■ Flexor Tenolysis With or Without Volar Capsular Release

- Open the wound using the prior incisions and identify the neurovascular structures first to protect them (**TECH FIG 2A**).
- The A1 pulley is released and a window is opened over the cruciate and A3 pulleys.
- The A2 and A4 pulleys are preserved as much as possible. If necessary, pulleys may be partially “vented” by making a longitudinal incision along the radial or ulnar border of the sheath.
- The superficialis tendon and the profundus tendon are examined at the level of the A1 pulley using an Allis clamp “turnkey” maneuver (**TECH FIG 2B**).
- Tenolysis knives or a Freer elevator can be used to free adhesions around the

tendon. There are often deep adhesions to the bone and between the FDS and FDP (**TECH FIG 2C–G**).

- If a PIP joint contracture exists, the volar plate can be transversely incised and the checkrein ligaments released.⁴
- Rarely, FDS may be sacrificed if dense adhesions and a tight sheath are encountered.
- If contracture of the skin is causing the motion limitation, then preoperative planning should include the design of a longitudinal incision with Z-lengthening at the flexion creases.

TECH FIG 2 • A. Limited flexor tenolysis for adhesions after a pinning of a proximal phalanx fracture. **B.** Turnkey motion demonstrating return of extension. **C.** Both the FDS and FDP tendons were isolated. The A4 pulley was previously excised during the initial repair and was not competent. **D–G.** Tenolysis through traction with an Allis clamp was sufficient to disrupt the adhesions and restore motion.

■ Intrinsic Release

- There are two types of intrinsic release:
 - The intrinsics can be released at the extensor hood.
 - The intrinsics can be released proximally off of the metacarpal in the intrinsic slide procedure, typically for intrinsic contracture resulting from compartment syndrome.
- Distal release is indicated for a positive Bunnell intrinsic tightness test. The PIP joint will have less flexion when the MP joint is extended and more flexion when the MP joint is flexed.
- The extensor hood is approached through a single midline dorsal incision or a double midaxial incision.

- The oblique fibers are identified in the distal third of the proximal phalanx.
- A triangular wedge of the oblique fibers is excised.
- Avoid cutting into the transverse fibers, which attach the proximal phalanx to flex the MP joint.
- Proximal release is indicated in patients with severe intrinsic tightness, where the MP joint is also affected.¹
- Proximal release consists of cutting the intrinsics proximal to the MP joint. Another alternative is an intrinsic slide where the intrinsics are released from the metacarpal. These procedures are typically performed in more severe intrinsic contractures such as those secondary to compartment syndrome.

PEARLS AND PITFALLS

Indications

- Tenolysis will not improve a stiff finger that has joint incongruity or malalignment.
- Wounds, swelling, and inflammation should be resolved before surgery.
- Nonoperative measures should be continued as long as progress is being made.
- The patient must agree to a strict post-op rehab program before surgery is considered.

Incision

- For multiple MP joint extension contractures, avoid a single transverse incision, as this will gap during early rehab.
- Anticipate soft tissue contractures and be prepared to perform Z-plasty or advancement flaps for coverage.

Sequential release

- Begin with releasing the tendon adhesions from the bone and skin.
- Release the capsule and then ligaments if necessary.
- Be mindful that intrinsic tightness may coexist and warrant release.

Rehabilitation

- Begin rehab immediately after surgery.

POSTOPERATIVE CARE

- All protocols should begin 24 to 48 hours after surgery.
- The quality of the tendon should be noted intraoperatively.

- Thin, frayed, and poorly vascular tendons are at risk for rupture with an aggressive protocol.⁵

Flexor Tendon Rehabilitation

- Good-quality tendon
 - 0 to 2 weeks: Edema control, volar thermoplast splint (wrist neutral, MP and IP joints 0 degrees) to be worn at night and in between exercises. AROM, tendon gliding, and place-hold exercises to be performed hourly with 10 reps each
 - 2 to 4 weeks: Continue above. Add blocking exercises to PIP and DIP. Add grasp, dexterity, and ADL exercises. Add scar management.
 - 4 to 8 weeks: Continue above. Add sustained gripping and progressive resistance. May add dynamic extension splint if needed.
 - 8 to 12 weeks: Add heavy resistance exercises and work simulation activities.
- Poor-quality tendon
 - 0 to 2 weeks: Edema control, volar thermoplast splint to be worn at night and in between exercises. The splint is fabricated to place the joints in full extension for extensor lag and in resting position for extension contracture. Passive flexion performed hourly.
 - 2 to 4 weeks: Add AROM, tendon gliding, and place-hold exercises to be performed hourly with 10 reps each. The splint is gradually brought to allow MP joint at 0 degrees by 4 weeks. Add scar management.
 - 4 to 8 weeks: Add blocking exercises to PIP and DIP. Add grasp, dexterity, and ADL exercises.
 - 8 to 12 weeks: Add sustained gripping and progressive resistance. May add dynamic extension splint if needed.
 - 12 weeks: Add heavy resistance exercises and work simulation activities.

Extensor Tendon Rehabilitation

- Good-quality tendon
 - 0 to 2 weeks: Edema control, volar thermoplast splint to be worn at night and in between exercises. Fabricate the splint to place the finger joints in extension for extensor lag and in resting position for extension contracture. AROM, gliding, place-hold, and blocking exercises performed hourly.
 - 2 to 4 weeks: Add grasp, dexterity, and ADL exercises. Add scar management.

- 4 to 8 weeks: Add sustained gripping exercises. At 6 weeks, add progressive resistance. May add dynamic flexion splint if needed.
- 8 to 12 weeks: Add heavy resistance exercises and work simulation activities.
- Poor-quality tendon
 - 0 to 2 weeks: Edema control, volar thermoplast splint to be worn at night and in between exercises. Fabricate the splint to place the finger joints in extension for extensor lag and in resting position for extension contracture. Tenodesis exercise, gentle AROM, gliding, and place-hold performed hourly.
 - 2 to 4 weeks: Add AROM and blocking exercises. Add scar management.
 - 4 to 8 weeks: Add grasp, dexterity, and ADL exercises.
 - 8 to 12 weeks: Add sustained gripping exercises and progressive resistance. May add dynamic flexion splint if needed.
 - 12 weeks: Add heavy resistance exercises and work simulation activities.

OUTCOMES

- Weeks et al. evaluated 789 stiff MP and PIP joints in 212 patients at a mean 3.4 months after injury. Exercises and dynamic splinting alone were effective in 87% of patients. MP joint range of motion (ROM) improved 32 degrees on average, while PIP joint ROM improved 36 degrees on average. Surgery was required for the remaining 13%.⁶
- Hunter et al. reported on 61 digits with PIP joint contractures treated nonoperatively with exercises and static or dynamic splints. Preoperative motion at the PIP joint range of motion was 24 to 67 degrees, which improved to 8 to 98 degrees.⁵
- Breton et al. reported on 75 digits that underwent postinjury zone II flexor tendon tenolysis. They noted a preoperative total arc of motion of 128 degrees and a postoperative arc of 192 degrees at 3 months. Flexor tendon rupture occurred in seven cases.⁷
- Yamazaki et al. noted that the preoperative range of motion was the strongest predictor of postoperative range of motion in patients undergoing flexor tenolysis after phalangeal fracture.⁸
- Adjunctive treatments such as indwelling local anesthesia catheters and continuous passive motion (CPM) devices have been described; however, limited evidence justifies their routine use. Schwartz and Chafetz noted no difference in gains in total arc of motion with CPM.⁹

COMPLICATIONS

- Tendon rupture can occur if tenolysis performed before repair site is healed.
- Tendon disruption can occur if the tenolysis erroneously strips the insertion site.
- Recurrence can occur if the patient is not compliant with rehab or if the zone of injury is too great.

41 Acute Repair of Extensor Tendon Injuries in Zones I to VI

CHAPTER

Michael Smith, Jacques A. Machol IV, and Neal Chen

DEFINITION

- The extensor apparatus of the hand is a delicate and complex system that works in synergy with the flexor system to facilitate gross and fine motor activity of the hand and digits.
- Extrinsic extensor function is provided to the digits by the extensor digitorum communis (EDC), extensor indicis proprius (EIP), and extensor digiti minimi (EDM). These muscles work in concert with the intrinsic muscles of the hand to provide extension of the proximal and distal interphalangeal (DIP) joints through the intrinsics' contributions to the extensor mechanism via the lateral bands.
- The extensor apparatus can be injured by blunt or sharp trauma, as well as by attrition from inflammatory conditions.

ANATOMY

- The extensor tendons can be divided into superficial and deep muscle groups.¹
- The superficial group includes the extensor carpi radialis longus (ECRL), the extensor carpi radialis brevis (ECRB), the EDC, the EDM, and the extensor carpi ulnaris (ECU).
- The deep group includes the extensor pollicis brevis (EPB), the extensor pollicis longus (EPL), and the EIP.
- The extensors are innervated by the posterior interosseous nerve (PIN) with the exception of the ECRB and ECRL, which are innervated by the radial nerve prior to the split into the PIN and the superficial radial nerve.²
- The ECRB may sometimes be innervated by the PIN after the radial nerve has

split.

- The extensor tendons travel through six separate dorsal compartments at the level of the wrist prior to entering the hand.
- The first dorsal compartment contains the abductor pollicis longus (APL) and the EPB tendons.
 - There is septation of this compartment in 20% to 60% of individuals, and it is common for the APL to have multiple tendon slips.³
- The second dorsal compartment contains the wrist extensors, the ECRB and ECRL.
 - The ECRB is located ulnarly in relation to the ECRL.
- The third dorsal compartment contains the EPL tendon and is just ulnar to Lister tubercle on the radius.
- The fourth dorsal compartment contains the EIP and EDC tendons. The PIN is also found within the base of this compartment.
 - The EIP can be identified at the level of the hand and wrist in that it:
 - Is ulnar to the index finger slip of the EDC
 - Has the distal most muscle belly
 - Is the deepest tendon proximal to the extensor retinaculum
 - Is not connected by juncturae tendinum
 - The EIP is absent in up to 1% of the population and can have multiple slips in up to 16% of the population.
- The fifth dorsal compartment contains the EDM and overlies the distal radioulnar joint (DRUJ).
 - The EDM is found ulnar to the EDC tendon to the small finger.
 - The EDC tendon to the small finger is often absent, and a double EDM tendon may occur in 80% to 90% of individuals.⁴
- The sixth dorsal compartment contains the ECU tendon.
- At the level of the hand, the tendons become flat and juncturae tendinum provides interconnections between the EDC tendons.
- At the level of the metacarpophalangeal (MCP) joint, the radial and ulnar sagittal bands form a sling around the extensor tendon and attach to the volar plate (**FIG 1A**).
- Distal to the MCP, the intrinsic muscles of the hand join the extensor tendons to form the extensor hood.

FIG 1 • A–C. Extensor apparatus at the digit.

- The central tendon trifurcates at the level of the proximal phalanx, with the radial and ulnar slips becoming the lateral bands and the central slip inserting into the base of the middle phalanx by providing proximal interphalangeal (PIP) joint extension.
- The interossei split into medial and lateral slips. The medial slip will insert

into the base of the proximal phalanx and functions to flex the MCP joint. The lateral slip will join with the lateral band of the common extensor tendon to form the conjoined lateral band. The radial and ulnar conjoined lateral bands will form the terminal tendon and insert onto the distal phalanx, extending the DIP joint (**FIG 1B,C**).

- The triangular ligament prevents the conjoined lateral bands from volar subluxation, and the transverse retinacular ligament prevents dorsal subluxation.¹
- By convention, the extensor tendons are divided into nine zones to assist in classification of extensor tendon injuries. Odd-numbered zones are located over joints, and even-numbered zones are located over the long bones (**FIG 2**):
 - Zone I includes the DIP.
 - Zone II is the middle phalanx.
 - Zone III is the PIP.
 - Zone IV is the proximal phalanx.
 - Zone V is overlying the MCP joint.
 - Zone VI is over the metacarpals.
 - Zone VII includes the carpus and extensor retinaculum.
 - Zone VIII involves the distal forearm, up to the musculotendinous junction of the tendons.
 - Zone IX involves the remaining part of the upper forearm.

PATHOGENESIS

- Extensor tendons can be disrupted in a number of ways.
- Disruption of the terminal tendon in zone I, resulting in a mallet finger, can occur either through an avulsion of the tendon from its insertion or a fracture of the base of the distal phalanx at the tendon insertion.
- The tendons can also be cut from a sharp laceration, and it is not uncommon to encounter tendon ruptures from attritional wear, from either inflammatory arthritis or other conditions such as prominent hardware.

FIG 2 • Extensor tendon zones.

NATURAL HISTORY

- Often, there is an extensor deficit when the tendon is not repaired. In some cases, such as mallet fingers, the patient can still have a functional hand, even with the extensor tendon left unrepaired.
- In other cases, such as a sharp laceration of the EDC at zone VII, there will be residual impairment.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients will often present with a history of a recent trauma in the instance of extensor tendon laceration or mallet finger (**FIG 3**).

- Pain and a history of a pop are common with a mallet finger injury.
- Patients with attritional rupture, especially patients with inflammatory arthropathy who already have some functional deficits in their hand, may not realize that one of their extensor tendons has ruptured.
- Initial evaluation should include a thorough physical examination, testing all flexor and extensor tendons, in addition to the digital neurovascular bundles.
- Upon initial inspection, attention should be paid to the resting cascade of the digits. If this is disrupted, there is a high likelihood of tendon injury.
- Wounds should be closely inspected and a determination made of the cleanliness, sharpness, size, location, and potential for injury with the wound.
- The function of each extensor tendon should be tested both with and without resistance. Test each finger individually as the juncturae tendinum may mask an injury.
- To test the EIP and EDM, ask the patient to keep the middle and ring fingers flexed into the palm and extend the index and small fingers.
- If there is pain and swelling of the PIP joint, coupled with a mild PIP extension lag or weak PIP joint extension against resistance, one must consider a central slip injury.
- The Elson test, in which the DIP joint will become rigid with attempted extension of the PIP joint from a flexed position, will confirm an early central slip injury. The DIP becomes rigid because the finger extends through the intact lateral slips.
- Active and passive range of motion of all the joints in the hand and wrist should be tested and recorded.

FIG 3 • Clinical appearance of a mallet finger (zone 1 extensor tendon injury). (Courtesy of Philip Blazar, MD.)

FIG 4 • Radiographic appearance of a bony mallet

injury. (Courtesy of Philip Blazar, MD.)

IMAGING

- Radiographs of the hand or digit should be taken in orthogonal planes after an acute extensor tendon injury. This will identify any associated fractures, such as in a bony mallet injury (**FIG 4**), and can also identify any foreign bodies remaining in the extremity after a sharp injury.
- Ultrasound can be a useful adjunct in the setting of a chronic tendon injury to determine the position of the proximal and distal tendon ends if direct repair is being considered.
 - If 4 to 6 weeks have passed since injury, or if the nature of the rupture was secondary to attritional rupture, direct repair often is not possible because of shortening of the proximal tendon, and reconstruction or transfer should be considered.
- MRI can also aid in determining the position of the tendon ends; however, this is an expensive modality and can be time-consuming to obtain in some institutions.
 - In doubtful cases, ultrasound can make a precise determination of the tendon status.

DIFFERENTIAL DIAGNOSIS

- Extensor tendon laceration or disruption
- Adhesions of the extensor tendon system
- Fracture
- PIN palsy
- Radial nerve palsy

NONOPERATIVE MANAGEMENT

- Nonoperative management of extensor tendon disruption is usually considered for soft tissue mallet finger injuries and closed central slip avulsions.
- In closed soft tissue mallet finger injuries, good results can often be obtained with full-time DIP extension splinting.⁵ The duration of immobilization varies, but we usually use an extension splint for 8 weeks followed by 4 weeks of night splinting.
 - Patient compliance is the most important factor for achieving good outcome with extension splinting of soft tissue mallet injuries. However, patients

should be counseled that they will likely have a small extensor lag and dorsal prominence either with or without operative treatment.

- Surgical indications for soft tissue mallet injuries are debated but traditionally include open injuries or mallet fractures with volar subluxation or a fracture fragment larger than 30% to 50% of the articular surface.
- If there is a closed injury to the central slip, the injury can be treated with extension splinting of the PIP joint. One must ensure that the full passive PIP joint extension and DIP flexion can be achieved in the splint.
- Full-time extension splinting is continued for 6 weeks, followed by 6 weeks of nighttime splinting.
- Active flexion exercises of the DIP during this period of immobilization can help pull the lateral bands dorsally and prevent volar subluxation of the bands, which can result in a boutonniere deformity.
- If the tendon injury is incomplete, greater than 50% of the tendon is intact, and there is no extensor lag or weakness on physical exam, tendon injuries can be treated nonoperatively with 1 or 2 weeks of splinting.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to undertaking surgical repair of the extensor tendons, one must ensure that they have performed a complete physical examination of the hand and upper extremity. Other tendon injuries, nerve injuries, fractures, or concomitant conditions that will need to be addressed surgically should be identified preoperatively.
- Radiographs should be obtained to rule out fracture, foreign body, or other etiology of tendon injury such as inflammatory arthritis or prominent hardware.
- If the tendon disruption is chronic, a detailed preoperative plan should be developed to include the possibility of tendon reconstruction or transfer if the tendon cannot be repaired primarily.
- If necessary, pinning of the PIP joint is considered.
- Any additional equipment that may be required to complete and protect a strong repair should be communicated to the operating room staff in advance, including hardware and intraoperative fluoroscopy.

Positioning

- The positioning for the techniques listed below is the same.

- The patient is placed supine on the operating room table.
- A hand and upper extremity table extension is attached to the table.
- A nonsterile tourniquet is applied to the upper arm over padding.
- The arm is pronated to expose the dorsum of the hand.
- One or two OR towels are fluffed and placed in the palm of the hand to keep the fingers extended.

Approach

- There are a number of described surgical approaches to the dorsum of the DIP, PIP, and MCP joints as well as the hand, wrist, and forearm.⁶
- In general, a longitudinal incision is preferred to allow the surgeon to extend the incision distally or proximally should the need arise.
 - We prefer to make a gentle S incision over the DIP joint, a radially based curvilinear longitudinal incision across the PIP and MCP joints and a straight longitudinal incision over the metacarpals, wrist, and forearm.
- The incision should take into consideration possible future procedures.
- If there is a laceration, this is usually extended proximally and distally in a longitudinal manner to fully explore the wound and injured structures.
- Distal to the carpus, there is not much subcutaneous tissue between the skin and the tendon layer. The dissection is brought down sharply to the level of the tendons or extensor retinaculum with care taken to preserve dorsal veins if possible.
- Once the level of the tendon is encountered, full-thickness skin flaps are raised for full exposure of the tendon ends or extensor retinaculum.
 - If the extensor retinaculum is to be opened, we prefer to identify the EPL exiting distally and open the retinaculum in line with the third dorsal compartment to ensure the EPL tendon does not get inadvertently transected.

TECHNIQUES

■ Repair of Open Mallet Injury (Zone I Injury)

- If the terminal tendon has been sharply transected, it is possible to perform a primary repair that is then supplemented with Kirschner wire fixation of the DIP joint in extension.

- Often, the pre-existing laceration can be incorporated into the incision and should be extended distally and proximally.
- Careful sharp dissection of the skin off the terminal tendon is performed, preferably with a flexible scalpel (Beaver Mini-Blade No. 67, Beaver-Visitec Int.).
- Once the terminal tendon has been exposed, insert the K-wire in retrograde fashion under C-arm fluoroscopy to hold the joint in extension while the tendon repair is being performed.
- A determination is made if there is enough remaining terminal tendon in the insertion of the distal phalanx to facilitate direct repair.
 - If there is enough tendon remaining, a four-strand repair is then performed using a 4-0 nonabsorbable braided suture, usually in doubled horizontal mattress configuration if possible or a figure-eight configuration.
 - If there is not enough tendon remaining for a primary repair, the proximal tendon end can be brought back to the insertion site of the distal phalanx and secured over a pullout suture button.
 - Repair using one or two microsuture anchors has been described; however, the insertion of the terminal tendon is immediately adjacent to the origin of the germinal matrix and the risk of iatrogenic injury to the nail bed makes this our less preferred technique.
 - A simpler method of repair involves dermatotendodesis (**TECH FIG 1**). With this method, one or two 2-0 nylon sutures are placed through the skin and tendon ends and sutured in a horizontal mattress fashion. The sutures are left for 3 weeks and then removed. Full-time splinting is continued for a total of 6 weeks and nighttime splinting for an additional 6 weeks.
- Once the repair is completed, the wound is copiously irrigated and the skin is closed with interrupted suture.
- The joint is protected with an extension splint for the length of time the pin is in place.
- We pull the pin at 4 to 6 weeks and continue with nighttime splinting for an additional 6 weeks.
- Active and passive range of motion at the PIP and MCP joints is encouraged to prevent stiffness.

TECH FIG 1 • Example of dermatotenesis performed in the ring finger after a zone I extensor tendon injury. (Courtesy of Philip Blazar, MD.)

■ Closed Mallet Fracture Pinning

- Ideally, before a closed mallet fracture is brought to the operating room for surgical repair, one should attempt to obtain radiographs with the digit held in extension at the DIP joint to see if fracture reduces easily.
 - If seen acutely, oftentimes the fracture will reduce well with extension of the digit.
- At the beginning of the procedure, the C-arm is brought in and joint is visualized radiographically.
- The DIP joint is then flexed in an attempt to bring the dorsal fragment as far distal as possible.
- One 0.028- or 0.035-in. Kirschner wire (K-wire) is then placed just proximal and dorsal to the dorsal fragment and driven across the DIP joint into the middle phalanx.
- The distal phalanx is then extended, and the K-wire should hold the dorsal fragment in a stable position as the phalanx reduces back to the fragment.
- Once adequate reduction has been achieved, a second K-wire is inserted in a retrograde fashion from the tip of the distal phalanx across the DIP joint and

into the middle phalanx.

- The DIP joint is protected with an extension splint throughout the time the pins are in place.
- The pins are pulled in the office at 4 to 6 weeks and nighttime splinting continues for an additional 6 weeks.
- Active and passive range of motion at the PIP and MCP joints is encouraged to prevent stiffness.

■ Zone III Central Slip Repair

- Zone III injuries overlie the PIP joint and involve the insertion of the central slip.
- If left untreated, the lateral bands will migrate volarly and a boutonniere deformity can develop (PIP joint flexion and DIP joint hyperextension).
- Central slip repair can be achieved by either primary repair in open lacerations or injuries or with suture anchors for avulsion injuries.
 - In 1999, Cluett et al.⁷ found similar biomechanical strengths for both suture anchor repair and primary repair.
- For lacerations, the laceration is extended proximally and distally to provide full exposure of the central slip and assess for any additional injury to the bone and PIP articular surface.
 - In closed, avulsion-type injuries, a dorsal curvilinear approach is utilized. This avoids making a longitudinal incision directly over the PIP joint.
- Skin flaps are raised sharply, taking advantage of the layer between the skin and the extensor apparatus.
- The injured central slip is identified and the tendon edges sharply debrided.
- The PIP joint is pinned in extension with a single 0.035-in. K-wire.
- If primary repair is to be performed, we prefer to perform the repair using a running, interlocking, horizontal mattress stitch popularized by Lee et al.⁸ using a 3-0 or 4-0 braided nonabsorbable suture.
- If suture anchor repair is to be performed, we prefer to place a single mini anchor into the central footprint of the middle phalanx. Care is taken to direct the suture anchor away from the base of the middle phalanx, so as not to penetrate the joint surface with the suture anchor.
- Postoperatively, active DIP motion is allowed. The pin is removed from the PIP joint at 3 weeks. At this point, begin gentle range of motion with hand

therapy and nighttime splinting as needed.

■ Zone V Extensor Tendon Repair

- Extensor tendon injury at the level of the MCP joint is the most common location for extensor tendon disruption (**TECH FIG 2A**).¹
- This zone is also where “fight bite” injuries often occur and special diligence must be made to ensure the MCP joint is thoroughly irrigated to prevent or treat an underlying septic arthritis of the MCP joint.
- There is a high incidence of partial tendon lacerations at this level. Extensor tendon lacerations involving more than 50% of the tendon should be repaired.
- Zone V injuries also must take into account the sagittal bands on the radial and ulnar sides of the MCP joint.
 - If the patient has an acute closed sagittal band rupture, it can often be treated with extension splinting of the MCP joint for 3 to 4 weeks with the PIP joint free.
- Extend the laceration both proximally and distally to ensure there is adequate exposure of the extensor tendon injury at this level and the MCP joint.
- Raise skin flaps with sharp dissection in the plane between the skin and the extensor apparatus.
- With open injuries, the MCP joint should always be explored and irrigated to prevent septic arthritis.
- Evaluate the sagittal band, and if it has been lacerated, perform a primary repair with a braided absorbable suture after the tendon has been repaired.
- At this level, the tendon is beginning to become thicker and may accommodate a core suture. If possible, we prefer to repair the tendon at this level with either a four-strand repair using 3-0 braided, nonabsorbable suture or the running, interlocking, horizontal mattress suture configuration described above (**TECH FIG 2B,C**).
- Postoperatively, there has recently been more emphasis on early, controlled mobilization of the repair.

TECH FIG 2 • A. Initial exploration of a zone V laceration with disruption of the extensor tendon to the ring finger. **B.** Zone VII extensor tendon laceration. **C.** Zone VII extensor tendon repair using core sutures. (Courtesy of Philip Blazar, MD.)

PEARLS AND PITFALLS

Counseling

- It is important to set realistic expectations with your patients for the treatment of mallet fingers. Long-term studies have shown that patients undergoing either surgical or nonoperative treatment will likely have some degree of mild extensor lag at the end of treatment.

Technique

- The dorsal skin can be thin and friable. Take extra care to handle the tissues delicately and develop full-thickness skin flaps.

Indications	■ In soft tissue mallet injuries, splinting is preferable to surgical repair as the skin is thin and sometimes can die after surgery. In addition, suture material can be prominent.
Suture anchors	■ If placing suture anchors into the distal phalanx for a zone I repair, be careful not to place the anchor into the germinal matrix.
Zone V injuries	■ Always explore the MCP joint in open injuries. Wound cultures should be obtained in “fight bite injuries.”

POSTOPERATIVE CARE

- Traditionally, extensor tendon repairs have been treated with initial immobilization for longer periods of time when compared with flexor tendon repairs.
- There is some evidence that for zone V and VI repairs, there are better short-term functional results with early mobilization protocols. There is some evidence of short-term superiority of early, controlled mobilization of extensor tendon repairs but no evidence of long-term superiority of early motion compared with immobilization⁹; plus, there is a higher risk of tendon repair rupture.^{10,11}
- For zone I, II, and III repairs, immobilization of the DIP and PIP joints respectively in extension for 6 weeks after repair is reasonable.
 - At that time, range of motion exercises can begin and nighttime splinting initiated for an additional 6 weeks.
 - Be sure to move the remaining joints of the finger to help prevent stiffness of the entire digit.
- For zone IV, V, and VI repairs, the MCP joints respectively are immobilized for about 4 weeks in extension, followed by gentle range of motion in conjunction with hand therapy. There is variation regarding immobilizing the PIP joints.

OUTCOMES

- Kalainov et al.¹² treated 21 patients with mallet fractures in which greater than one-third of the articular surface was involved with splinting in a 2005 retrospective study. They had good results in terms of pain and function, but their follow-up averaged only 2 years.
- Outcomes of surgical treatment for mallet injuries have been comparable across the various techniques. Most patients will have an extensor lag from 2 to

7 degrees and flexion ranged from 67 to 78 degrees.^{13–16}

- Pratt et al. reported on 27 patients who underwent zone III repairs and were treated with a postoperative protocol that consisted of static immobilization for 3 weeks and early controlled motion for an additional 3 weeks. Twenty-two of 27 patients had good results with mean PIP flexion of 94 degrees. Five fingers had extension lags of an average of 6 degrees.¹⁷
- Newport et al. reported on 101 digits that underwent extensor tendon repair and were treated postoperatively with static splinting.¹⁸ They found that patients with associated injuries (fracture, dislocation, flexor tendon injury) and distal repairs (zones I–IV) did worse than those without injuries and proximal repairs, with flexion loss being the most significant complication.

COMPLICATIONS

- Infection
- Tendon rupture
- Extensor lag
- Wound dehiscence
- Adhesions and stiffness
- Nail deformities

Stabilization of Extensor Carpi Ulnaris Tendon Subluxation With Extensor Retinaculum

42

CHAPTER

Michael Smith, Jacques A. Machol IV, and Neal Chen

DEFINITION

- Symptomatic recurrent extensor carpi ulnaris (ECU) subluxation over the ulnar head with forearm rotation can be a cause of ulnar-sided wrist pain. Not all patients with subluxation of the ECU are symptomatic, and painless subluxation is not an absolute indication for surgery.
- Symptomatic ECU instability manifests in patients who play sports such as tennis, hockey, squash, golf, or baseball.
- It is suspected that snapping of the ECU over the ulnar head with resisted supination, flexion, and ulnar deviation is the mechanism that leads to symptoms.

ANATOMY

- The ECU tendon runs through the sixth dorsal compartment following an angular path across the ulnar head as it travels from its muscle origin on the lateral epicondyle to its insertion on the base of the fifth metacarpal.
- The ECU ulnarly deviates and extends the wrist. The ulnar deviation is counterbalanced by the radially deviating forces of the abductor pollicis longus, extensor carpi radialis longus, and the extensor carpi radialis.
- The ECU tendon lies just dorsal to the flexion/extension axis of the wrist; therefore, the tendon is at risk for subluxation volar to the flexion/extension axis with hypersupination of the forearm and flexion with ulnar deviation of the wrist.¹

- The ECU tendon is stabilized by the extensor retinaculum.
- The ECU tendon runs through a fibro-osseous tunnel at the level of the distal ulna called the ulnar groove.
 - The average ECU groove depth measures approximately 1.4 mm, and the radius of curvature is approximately 7.0 mm.²
- In addition, the ECU has its own subsheath, which consists of an overlying band of connective tissue measuring 1.5 to 2.5 cm in length that functions to keep the ECU tendon within the ulnar groove.
- There are transverse fibers of the medial wall of the ECU compartment that extend proximally and become confluent with the ECU epimysium. These fibers help prevent volar subluxation of the tendon during supination.^{2,3}
- The ECU subsheath stabilizes the ECU during forearm rotation, while the extensor retinaculum helps prevent bowstringing of the extensor tendons.
- The ECU subsheath also contributes to the dorsal portion of the triangular fibrocartilage complex.
- The distal subsheath contributes more to ECU stability than does the proximal half of the subsheath.⁴
- Wrist flexion and supination are positions of relative instability for the ECU subsheath.⁴

PATHOGENESIS

- Incompetence of the ECU subsheath, whether through attritional wear or acute traumatic injury, is thought to lead to ECU instability.
- Laxity in the ECU subsheath and painless snapping over the ulnar head may be a normal variant, especially in individuals that are ligamentously lax.
- It is proposed that traumatic wrist flexion, ulnar deviation, and supination can result in rupture of the ECU subsheath from its ulnar attachments and lead to the subluxation of the tendon out of the distal ulnar groove.¹
- Symptomatic patients may demonstrate a snap when the wrist is placed in the at-risk position of flexion, ulnar deviation, and supination.
- ECU instability injuries were classified by Inoue and Tamura and separated into three distinct types.
 - The ECU subsheath can have detachment along the ulnar border (type A), the radial border (type B), or a periosteal detachment with expansion of the sheath, creating a false pouch that allows subluxation of the tendon from the ulnar groove (type C).^{5,6}

NATURAL HISTORY

- If left untreated, chronic instability of the ECU tendon can exacerbate ECU tendinopathy as the tendon snaps over the ulnar prominence of the ulnar groove.
- Some authors have theorized that chronic dislocation of the ECU tendon may lead to distal radioulnar joint (DRUJ) instability and eventual degenerative changes at the DRUJ. This phenomenon is uncommon.
- There are some patients who have naturally lax ligaments and have a degree of subluxation of the ECU tendon without previous injury. Their ECU instability is often bilateral and asymptomatic and found incidentally on exam.
 - In general, we recommend observing these patients.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients are often younger and participate in stick or racket sports such as tennis, golf, baseball, or hockey.
- Patients will complain of recurrent, painful snapping over the dorsoulnar wrist with wrist supination and pronation that limits their participation in sports, hobbies, or activities of daily living.
- There may be a history of a specific, acute injury.
- On physical exam, the ECU tendon can be palpated subluxating over the ulnar head with circumduction of the wrist.
 - Sometimes, supination and ulnar deviation against resistance are required to produce the snapping.
- If the ECU is irritated, it will often be most painful with full passive radial wrist flexion.
- Occasionally, the clinical exam is inconclusive if the patient is not able to voluntarily subluxate the ECU tendon.
- Painful subluxation of the ECU tendon is an important component of the physical examination, and the surgeon should be cautious if contemplating surgical treatment in the patient who does not have painful demonstrable ECU instability.
- Careful examination of the contralateral wrist should be done to ensure that the patient does not have asymptomatic subluxation of the ECU tendon as a natural variant and the patient's complaints do not have another etiology.
- Other etiologies for the patient's pain are ruled out, such as ulna impaction, ECU tendinosis, DRUJ instability, LT instability, or TFCC tears.

IMAGING

- Routine anteroposterior, lateral, and oblique radiographs of the wrist are obtained to rule out other pathologies that may be causing ulnar-sided discomfort such as fracture or DRUJ arthritis.
- It is important to note positive ulnar variance, as this can indicate ulnocarpal impaction.
- MRI is an option to evaluate for tendon subluxation; however, this is often a dynamic phenomenon that may not be visualized using a static MRI.
- Some authors suggest performing an MRI with both wrists positioned in pronation, neutral, and supination. This provides a comparison with the contralateral wrist to show the ECU tendon within the ulnar groove in all three positions. However, the usefulness of this imaging technique is debated.
- Other pathologies, such as TFCC tears, ECU tendonitis, or longitudinal tears, may be visualized with MRI, but the clinical significance of these findings needs to be considered thoughtfully.
- Dynamic ultrasound may demonstrate ECU subluxation out of the ulnar groove for patients in whom there was not definitive snapping or subluxation elicited during physical exam.⁷⁻⁹ The role of dynamic ultrasound is still in evolution.

DIFFERENTIAL DIAGNOSIS

- ECU tendonitis
- Triangular fibrocartilage complex tear
- Ulnocarpal impaction
- Carpal instability
- DRUJ instability
- DRUJ arthritis
- Ulnar nerve entrapment

NONOPERATIVE MANAGEMENT

- In acute injuries, 4 to 6 weeks of either a long-arm or Muenster cast immobilization is usually sufficient.
- Some authors recommend immobilizing in pronation and slight radial deviation, which allows the ECU subsheath to heal to the ulnar edge of the ulnar groove.¹
- After cast removal, a custom splint is applied and progressive return to activity

is begun in conjunction with occupational therapy.

- Full, unrestricted activity is usually achieved by 3 months if the patient is no longer painful.
- After treatment, some patients will have asymptomatic subluxation.

SURGICAL MANAGEMENT

- For patients in whom symptomatic instability of the ECU tendon persists after a period of immobilization and therapy, operative treatment is considered (**FIG 1**).
- If the ECU sheath is incompetent, a retinacular sling reconstruction should be elected. An ulnar groove deepening is performed only if the sheath is competent.
 - Some authors prefer sling reconstruction for all cases.

Preoperative Planning

- If a patient has an MRI present, it is useful to evaluate the anatomic details to understand if there is a type A, B, or C subluxation.

Positioning

- The patient should be positioned supine on the operating room table with the operative extremity on a hand or upper extremity table.
- Prior to draping the arm, perform an exam under anesthesia to recreate the ECU instability. It is important to note the position of instability preoperatively so one can confirm that the stabilization is effective once completed.
- A nonsterile tourniquet is placed on the upper arm to facilitate hemostasis.
- The arm is held in pronation to facilitate a dorsal approach to the ECU tendon.

FIG 1 • Anatomic ECU tendon sheath reconstruction. **A.** Exposure of the 6th dorsal compartment and elevation of the extensor retinaculum. **B.** Imbrication of the extensor retinaculum and subsheath. **C.** Final fixation of the extensor retinaculum and subsheath after imbrications.

TECHNIQUES

■ Exposure

- The arm is exsanguinated and the tourniquet is inflated.

- A 5-cm longitudinal incision is made overlying the sixth dorsal compartment and ECU tendon (**TECH FIG 1**).
- After the skin is incised, blunt dissection is carried out through the subcutaneous fat to identify and protect the dorsal cutaneous branch of the ulnar nerve.
- The extensor retinaculum over the sixth compartment should be sharply incised in a longitudinal fashion on its ulnar-most border and the retinaculum carefully dissected off of the underlying ECU subsheath.

TECH FIG 1 • Marked incision for ECU retinacular sling reconstruction. (Courtesy of Philip Blazar, MD.)

■ Retinacular Sling Reconstruction of the ECU Subsheat

- The extensor retinaculum is carefully dissected from its ulnar border to expose the ECU subsheath (**TECH FIG 2A**).
- Once the ECU subsheath is fully exposed, the type of pathology (type A, B, or C) of the subsheath is noted and the wrist is taken through a full arc of motion from pronation to supination to gauge the behavior of the tendon through wrist range of motion.
- At the level of the ECU subsheath, overlying the ulnar groove, a 3-cm

rectangular flap of retinaculum is developed starting at the second compartment; the base of which is the septum between the fifth and sixth dorsal compartments (**TECH FIG 2B**).

- This sling of retinaculum is then passed from radial to ulnar, volar to the ECU tendon, and folded back to the base of the flap (**TECH FIG 2C**).
- A trial stitch should be placed in order to assess the tightness of the sling in pronation, neutral, and supination in both wrist flexion and extension (**TECH FIG 2D**).
- The sling should not constrict the tendon, but it must still prevent subluxation of the ECU tendon about the ulnar head.
- The flap is sutured to itself using 3-0 nonabsorbable, braided suture.
- The remainder of the extensor retinaculum is anatomically repaired to ulnar border of the retinaculum using an absorbable suture.
- The tourniquet is let down, and hemostasis is confirmed.
- The wound is copiously irrigated, the dorsal incision is sutured, and the patient is placed into a sugar-tong splint with the wrist in mild pronation, extension, and radial deviation.

TECH FIG 2 • A. The extensor retinaculum flap is carefully dissected off the underlying ECU subsheath; this photograph also demonstrates a tear in the ECU subsheath. **B.** The extensor retinaculum rectangular flap is marked. **C.** The extensor retinaculum flap is laid over the ECU tendon in order to ensure adequate length. **D.** The extensor retinaculum flap is provisionally stitched, and stability is confirmed. (Courtesy of Philip Blazar, MD.)

■ Distal Ulnar Groove Deepening

- A dorsoulnar incision is made along the distal ulna starting 5 cm proximal to the wrist and ending 1 cm proximal to the joint (see **TECH FIG 1**).
- The dorsal sensory branch of the ulnar nerve is identified and protected.
- The extensor retinaculum is divided over the ulnar aspect of the sixth dorsal compartment, and care is taken to preserve flaps of retinaculum for later repair.
- The dissection is taken down sharply to the bone along the volar border of the ECU tendon subsheath.
- The ECU tendon within its subsheath is elevated dorsally by sharp subperiosteal dissection to the radial attachment of the subsheath.
 - The tendon subsheath is not routinely opened. However, if one suspects a longitudinal tear of the ECU tendon or other intratendinous pathology, the

subsheath can be opened at this point and the tendon pathology addressed.

- A power bur is then used to deepen the distal ulnar groove by 2 to 3 mm within the central groove. The groove is deepened until the ECU subsheath no longer subluxates with forearm rotation.
 - An alternative method is to perforate the cortex with a small drill or K-wire and then impact the cortex with a bone tamp so it sits deeper than the adjacent cortex.
- The ECU subsheath is reduced into the reconstructed groove, and two suture anchors are placed along the ulnar margin of the groove to maintain reduction.
 - The suture anchors are passed through the ulnar border of the ECU subsheath in a horizontal mattress pattern, and any redundant sheath is imbricated with the sutures.
- The sutures are tied, and the ECU tendon with its subsheath is secured to the distal ulna.
- The wound is copiously irrigated with normal saline.
- The tourniquet is let down, and hemostasis is obtained.
- The extensor retinaculum is repaired with an absorbable braided suture, and the subdermal and epidermal layers are then closed.
- A long-arm splint is applied with the elbow in 90 degrees of flexion and the wrist in neutral.

PEARLS AND PITFALLS

Approach

- Identify and protect the dorsal cutaneous branch of the ulnar nerve throughout the procedure.
- Inspect the ECU subsheath for injury or attenuation and determine if the subsheath can be repaired or will require reconstruction.

Ulnar groove deepening

- If the ulnar groove appears shallow, plan to perform an ulnar groove deepening.

Stability

- Be sure to check stability in extremes of ulnar deviation and supination with wrist flexion to ensure the ECU is stable before leaving the operating room.

Pitfalls

- Avoid injury to the dorsal cutaneous branch of the ulnar nerve with gentle retraction and protection throughout the procedure.
- Avoid overtightening the extensor retinaculum sling. The tendon should glide freely through the sling at the conclusion of the operation.
- Suture anchors placed into the deepened groove may inadvertently capture the ECU tendon.

Postoperative care

- Counsel patients that recovery can take 3–6 mo from the date of operation and they will need a period of immobilization and therapy after the operation.

POSTOPERATIVE CARE

- The wrist is initially immobilized in a sugar-tong or long-arm splint in the immediate postoperative period.
- At 2 weeks, the patient is converted to a Muenster-style orthoplast splint to prevent pronation and supination of the forearm but to allow elbow flexion and extension.
- At 6 weeks, occupational therapy is initiated beginning active and active assisted range of motion.
 - Passive range of motion and stretching are added progressively if needed.
 - The patient is advised to avoid forceful supination and flexion and heavy lifting during the rehabilitation period.
- Strengthening activities are initiated around 3 months postoperatively.

OUTCOMES

- A number of case reports and small case series have described the various techniques and outcomes for ECU tendon stabilization, but there is no level I evidence for surgical treatment of ECU instability.
 - Allende and Le Viet reported that 23 of 28 patients had good or excellent results at an average follow-up of 23 months after extensor retinaculum sling stabilization of the ECU tendon.⁶
 - MacLennan et al.⁹ reported improvements in DASH scores at 31 months after groove deepening.

COMPLICATIONS

- Injury to the dorsal cutaneous branch of the ulnar nerve
- Recurrent subluxation of the ECU tendon

- Infection
- Complex regional pain syndrome
- Decreased range of motion
- Decreased grip strength

CHAPTER Trigger Finger Release

Donato Perretta, Jacques A. Machol IV, and Neal Chen

DEFINITION

- Trigger digit, also known as stenosis tenosynovitis or tenovaginitis (tendon sheath inflammation), is a pathology characterized by painful locking or clicking of the fingers or thumb as a result of impaired gliding of the flexor tendon at the level of the A1 pulley.

ANATOMY

- The proximal edge of the A1 pulley begins approximately at the level of the metacarpal heads of the fingers. This corresponds to the distal palmar crease.
 - For the index finger, this line can be extrapolated radially.
 - In the thumb, it is at the level of the proximal digital crease.

PATHOGENESIS

- Trigger digit is caused by a thickening of the flexor tendon sheath, specifically the A1 pulley.
- The pathological change in the A1 pulley has been described as fibrocartilaginous metaplasia.¹
- Over time, the flexor tendon can also undergo degenerative changes consistent with tendinosis.² The resulting imbalance in the size of the A1 pulley and the enclosed flexor tendons causes catching and locking.

NATURAL HISTORY

- The thumb is the most commonly involved digit.³
- Women are more commonly affected than are men.
- There are no long-term studies documenting the natural history of untreated

trigger finger.

- The condition may progress from tenderness at the A1 pulley to painless clicking to painful triggering of the finger that requires passive manual extension.
- Over time, flexion deformities may develop at the PIP joint due to persistent triggering.
- The condition is more common and progresses more often in patients with endocrinopathies and inflammatory arthritides.²

PATIENT HISTORY AND PHYSICAL FINDINGS

- Tenderness over the A1 pulley
- Palpable nodule over the A1 pulley
- Painful popping or catching of the digit with flexion
- Inability to actively extend the PIP joint from a flexed position
- Flexion contracture of the PIP joint with long-standing trigger finger

IMAGING

- Imaging is not necessary.

DIFFERENTIAL DIAGNOSIS

- Locked MP joint. The collateral ligament can become entrapped over a metacarpal head osteophyte. This usually presents as inability to extend the digit fully after the collateral is locked.
- Early swan-neck deformity with snapping of lateral bands as they dislocate dorsally
- Subluxation of the extensor tendon after sagittal band rupture. In this situation, the finger can be passively extended and then can be actively maintained in extension. However, if the finger is flexed, the extensor tendon will subluxate and the finger cannot actively extend fully.

NONOPERATIVE MANAGEMENT

- Corticosteroid injection into or superficial to the A1 pulley is the first-line treatment. This is usually performed using a 25-gauge needle with 0.5 cc of 1% plain lidocaine and 5 mg of Kenalog. Injections can eliminate symptoms, but the duration of their effect is unpredictable.
- One study showed that after injection, 56% of the digits had a recurrence of symptoms within a year. Recurrence was associated with younger age,

insulin-dependent diabetes mellitus, involvement of multiple digits, and a history of other tendinopathies.

- Symptoms often recurred several months after the injection.⁴
- Taras et al. reported that extra-sheath injections may be more effective than those administered within the sheath.⁵
- Splinting the MCP joint of the affected digit in extension is another commonly used nonoperative measure. Colbourn et al.⁶ demonstrated short-term improvement in symptoms with a removable orthoplast splint in 28 patients.

SURGICAL MANAGEMENT

- Percutaneous A1 pulley release is a well-described treatment option that has been reported to be safe and effective.⁷ The A1 pulley is released under local anesthesia using a large-bore needle while the patient intentionally triggers the affected finger.
- Open A1 pulley release is our preferred treatment method in a patient with recurrent symptoms after two injections.
- Patients with rheumatoid hand deformity often develop tenosynovitis of the flexor tendons. In this group of patients, A1 pulley release is not recommended, as it can result in increased ulnar drift of the fingers. Instead, annular pulley-sparing tenosynovectomy and carpal tunnel release should be performed. The ulnar slip of the superficialis can be resected from the middle phalanx to reduce the bulk of tendon within the flexor sheath.⁸

FIG 1 • Trigger finger incisions for single-digit surgery (A,B) and for multiple-digit surgery (C).

Positioning

- Supine with hand table
- The procedure may be performed with a brachial tourniquet with infiltration of local anesthetic into the surgical site.
- Intravenous sedation can be used as an adjunct.

Approach

- If one digit is to be addressed, then a longitudinal or oblique incision is made over the A1 pulley (**FIG 1A,B**). The pulley lies over the metacarpal head.
- If adjacent digits are to be addressed, a transverse incision is used. Often, this is aligned within the distal palmar crease (**FIG 1C**).

TECHNIQUES

■ Open A1 Pulley Release

- After skin incision, blunt dissection is made down to the A1 pulley (**TECH FIG 1A**).
 - Retractors are placed on either side of the pulley to prevent damage to the neurovascular bundles.
- A no. 15 blade is used to incise the A1 pulley in line with the longitudinal axis of the finger in the center of the flexor tendon/pulley (**TECH FIG 1B**).
- Some surgeons describe an A0 pulley proximally or a proximal fascial band that may result in persistent triggering.
- One should be cautious not to release the A2 pulley distally.
- The patient is asked to actively flex the fingers down to the palm, and the presence of triggering is assessed. This can be done passively if the patient is unable to comply.
- If triggering continues once the entire A1 pulley has been released, excision of the ulnar slip of the FDS tendon is an option. This can be performed through a Bruner-type volar incision over the PIP joint.
- The skin is closed with 5-0 nylon interrupted sutures.

TECH FIG 1 • **A.** Identification of the A1 pulley. **B.** Flexor tendon is visible after A1 pulley release.

PEARLS AND PITFALLS

Incomplete release

- The entire A1 pulley should be divided under direct visualization.

Persistent triggering after complete A1 pulley release

- There is a band, which some call the A0 pulley, which lies proximal to the A1 pulley. This should be released if the finger still triggers after A1 pulley release.
- If triggering is still present after A1 pulley, one slip of the FDS tendon should be excised. Usually, the radial slip is preserved and the ulnar slip excised to help avoid ulnar drift of the digits.

Injury to neurovascular bundle

- Care must be made during exposure to protect the neurovascular bundle during A1 pulley release.

Bowstringing

- Release of the A2 tendon sheath distal to the A1 pulley may lead to tendon bowstringing.

POSTOPERATIVE CARE

- A sterile dressing is placed. It is removed on postoperative day 3, and digital motion is encouraged.
- Sutures are removed 10 days after surgery.
- No formal therapy is indicated.

OUTCOMES

- Outcomes are generally excellent.
- Recurrence rates after surgery have been reported at 3%.
- Rates of reoperation have been reported at 1% to 2.4%.³⁻⁵

COMPLICATIONS⁹

- Infection (superficial or deep)
- Digital nerve or artery injury
- Incomplete release
- Persistent swelling and pain
- Flexion contracture
- Tendon bowstringing

44 First Dorsal Compartment (de Quervain) Release

CHAPTER

Donato Perretta, Jacques A. Machol IV, and Neal Chen

DEFINITION

- de Quervain syndrome is defined as tenosynovitis of the first dorsal compartment. The first extensor compartment contains the tendons of the extensor pollicis brevis (EPB) and abductor pollicis longus (APL).

ANATOMY

- The first dorsal compartment is the most radial extensor compartment at the level of the wrist and contains the tendons of the EPB and APL. The extensor retinaculum is the ceiling of the compartment.
- The APL may have multiple slips, and there may be separate subsheaths for both the APL and EPB.¹ The APL is more radial and volar, whereas the EPB is more ulnar and dorsal. The separate subsheath for the EPB may be missed if one does not look for it routinely.

PATHOGENESIS

- Although this is commonly described as tendonitis, histologic markers of inflammation are not present. The tendon sheath of the first compartment is thickened, and there is deposition of mucopolysaccharide, an indicator of myxoid degeneration.²
- The disease is also common in pregnancy and the postpartum interval. It often is self-limited and resolves with birth or the termination of breast-feeding.³

PATIENT HISTORY AND PHYSICAL FINDINGS

- Tenderness at the radial styloid in the first compartment
- Positive Finkelstein test (radial wrist pain with ulnar deviation of the wrist while the thumb is held into the palm)

IMAGING

- Radiographs of the wrist are useful if the diagnosis is in doubt. They can help exclude other degenerative conditions about the wrist and thumb.

DIFFERENTIAL DIAGNOSIS

- Radiocarpal arthritis
- Intersection syndrome (pain and crepitus in the distal forearm at the intersection of the first and second dorsal compartments)
- Thumb basal joint arthritis
- Scaphoid or carpal fracture
- STT arthritis
- Injury or irritation of the superficial branch of the radial nerve

NONOPERATIVE MANAGEMENT

- A forearm-based thumb spica splint is usually the first-line treatment.
- Steroid injection into first dorsal compartment sheath is an effective treatment. Our preference is to use 0.5 cc of 1% lidocaine and 0.5 mg of dexamethasone.
 - About 80% of patients will experience symptomatic improvement after one injection, and half will remain symptom-free at 1 year.⁴
- Steroid injection may be more effective than splinting for breast-feeding mothers.³
 - Some pediatricians or obstetricians object to the use of steroid injections while breast-feeding, however, and this should be discussed with other caregivers. There is concern that trace amounts of steroid can enter the breast milk and that lactation can be affected after injection.⁵

SURGICAL MANAGEMENT

- First dorsal compartment release is indicated after failure of nonoperative management.
- Conservative measures such as splinting and injection should be attempted before surgical intervention.

Positioning

- Supine, with hand table, with brachial tourniquet. Local anesthetic infiltration is used.

Approach

- Release of the compartment can be accomplished with a chevron, transverse, or longitudinal incision.

TECHNIQUES

■ First Dorsal Compartment Release

- A 2-cm incision is made 1 cm proximal to the distal extent of the radial styloid (**TECH FIG 1A**).
- The first dorsal compartment is exposed (**TECH FIG 1B,C**).
- Care is taken to avoid injuring the superficial branch of the radial nerve, which travels superficial to the extensor retinaculum.
- Injury to the radial sensory nerve can be minimized with retractors placed proximally and distally rather than dorsally/volarly.
- The first dorsal compartment is released longitudinally at the dorsal edge (**TECH FIG 1D**). This prevents volar subluxation of the tendons.
- The APL and EPB are wholly inspected to ensure that all subsheathes have been released.
 - Up to half of patients may have separate compartments for these tendons. It is theorized that these accessory compartments predispose to de Quervain's.⁶
- Interrupted buried 3-0 absorbable monofilament sutures are used for wound closure, and Steri-Strips are applied.
- A thumb spica plaster splint is applied for 7 to 10 days.

TECH FIG 1 • A. The chevron (*dashed lines*) is the preferred incision for release of the first dorsal compartment. **B.** Sheath of first dorsal compartment exposed. **C.** Once the skin is incised, care is taken to avoid the radial sensory nerve. The blood on the sheath is from the preoperative local anesthetic injection. **D.** First dorsal compartment tendons exposed. The sheath is released from the dorsal side to prevent volar subluxation of the tendons. The forceps are holding the sheath. The APL and EPB are visible, with the APL being the more volar structure.

PEARLS AND PITFALLS

Nerve injury

- Identify the superficial branch of the radial nerve. Aggressive retraction results in a problematic injury to the nerve and persistent pain.

Volar tendon

- Leave a cuff of tissue volarly when incising the sheath.

subluxation

Incomplete release

- Be sure to release both the EPB and APL as they often have separate subsheaths.

POSTOPERATIVE CARE

- The splint is removed in 7 to 10 days, and immediate at-home range-of-motion exercises are initiated. Typically, there is no need for formal therapy.

OUTCOMES

- A consecutive series of 94 patients found symptom resolution in 100% of patients.
- There were six perioperative complications, including one superficial wound infection, one delayed wound healing, and four transient lesions of the radial sensory nerve.⁷

COMPLICATIONS

- Infection
- Injury to superficial radial nerve
- Scar tenderness

Section X: Flaps and Microsurgery

45 Flap Coverage of Fingertip Injuries

CHAPTER

Kate Elzinga and Kevin C. Chung

DEFINITION

- Fingertip injuries are defined as injuries that occur distal to the insertion of the flexor and extensor tendons of the finger.¹
- Fingertip injuries are the most common hand injuries; the fingertips are relatively unprotected compared to the rest of the hand.
- The fingertip plays an important role in fine motor skills, precise sensation, and hand aesthetics. Reconstruction of fingertip injuries can restore form and function for injured patients.
- The goals of fingertip reconstruction include the following:
 - Durable coverage
 - Preservation of sensation
 - Preservation of length
 - Maintenance of distal interphalangeal (DIP) joint function
 - Optimized appearance
 - Minimized donor-site morbidity
 - Permitting early return to work and recreational activities
 - Minimizing pain, in the short and long term
- Fingertip flaps are used to cover injuries with exposed bone and tendon. Local (V-Y advancement) and regional (thenar, cross-finger) flaps are useful options.
- Local flaps, such as the Atasoy-Kleinert V-Y advancement flap,² are the simplest flaps used for reconstruction; immobilization is not required and

donor-site morbidity is minimal.

- Regional flaps are employed when local flaps are not available because of the injury geometry (regional flaps are best used for volar oblique injuries) and size (local flaps can only be advanced 1 cm). Regional flaps require two-stage procedures and immobilization of the injured, and often adjacent, finger.

ANATOMY

- The volar fingertip is covered with glabrous skin. The epidermis is thick, and papillary ridges are prominent.
- The fingertip pulp is composed of fibrofatty tissue that is stabilized volarly by fibrous septa that run from the distal phalanx periosteum to the dermis and laterally by Grayson and Cleland ligaments.
- The proper digital nerve trifurcates distal to the DIP joint, sending branches to the nail bed, distal fingertip, and volar pulp. The proper digital artery also trifurcates at this level, sending two branches dorsally and one branch laterally.

PATHOGENESIS

- Trauma is the most common cause of fingertip injuries.³
- Common mechanisms of fingertip injuries include sharp injuries from a knife, power tool, or lawn mower and crush injuries from closing a door, a strike with a hammer, dropping a heavy object, becoming trapped in machinery, or sporting activities.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A careful patient history and physical examination help determine which flap options are suitable for a particular patient.
 - Some patients may prefer rapid return to their work and avocations and will refuse fingertip reconstruction, opting for fingertip amputation instead.
- A focused hand history must include age, sex, hand dominance, and occupation and recreational activities. The patients' goals are explored, including their need to return to work, their availability and willingness to undergo secondary procedures and hand therapy, and the importance of appearance.
 - Aesthetic outcome may be more important for females and patients from certain Asian cultures.
- Important considerations from the patient's past medical history include smoking, diabetes mellitus, peripheral vascular disease, connective tissue

disorders, arthritis, Dupuytren disease, and previous hand injuries.

- The presence of comorbidities may affect reconstruction options offered given their effect on flap vascularity and wound healing.
- Key injury factors to consider include the time of injury, mechanism of injury (sharp vs crush), contamination, and associated injuries.
- On physical examination, the defect size is measured. The level of the injury is assessed clinically and using radiographic imaging.
- Missing tissue (skin, pulp, bone, nail) and exposed structures are documented. The geometry of the injury is assessed and classified as volar oblique, transverse, or dorsal oblique (**FIG 1**).¹
- Tissue contamination is assessed, and any early signs of infection are noted.
- Surrounding tissues and digits are examined as potential donor sites.

FIG 1 • The angle of amputation is assessed to aid in selection of an appropriate local or regional flap for fingertip coverage. Volar oblique injuries with no exposed bone (*a*) can heal by secondary intention. Volar oblique injuries with exposed bone (*b*) can be reconstructed with regional flaps (thenar flap, cross-finger flap). Transverse (*c*) and dorsal (*d*) oblique injuries with exposed bone can resurfaced with a volar

V-Y advancement flap.

- The integrity of the flexor digitorum profundus (FDP) and extensor digitorum communis (EDC) tendons is tested; it is important not to miss an associated jersey finger or mallet finger injury.

IMAGING

- Plain radiographs can identify fractures of the finger and the presence of a foreign body.
- Three radiographic views of the finger and amputated part should be obtained following a fingertip amputation.

NONOPERATIVE MANAGEMENT

- Small defects (less than 1 cm²) with no exposed bone can be treated nonoperatively.⁴
- Dressing changes are performed daily to maintain a clean moist wound bed as the wound heals by secondary intervention over several weeks.
- Outcomes are typically excellent in these cases as glabrous sensate skin heals over the exposed soft tissues.⁵
- Immobilization is not required and range-of-motion exercises are performed throughout.

SURGICAL MANAGEMENT

- Full-thickness skin grafts (FTSGs) can be considered for coverage of large soft tissue avulsion injuries without exposed bone or tendon.
- The glabrous skin of the hypothenar eminence is the preferred harvest site for volar skin defects. Palmar skin is an excellent donor site for structure and color matching of the fingertip skin; the resultant scar from the palm can be rather imperceptible.
- Skin grafting promotes faster wound coverage, but sensation, color, and durability are inferior to secondary healing.⁵

FIG 2 • Volar oblique fingertip defects can be closed with a V-Y flap. Distally, the fibrous septa are released from the undersurface of the flap to allow advancement of the flap distally into the defect, where it is sutured over the wound.

- Replacement of amputated tissue as a composite graft may be considered; outcomes are best for pediatric patients younger than 6 years of age within 5 hours of the amputation.⁶

- Fingertip flaps preserve finger length. Early coverage of exposed bone and tendon decreases the risk of osteomyelitis and tendon desiccation. Protecting the terminal phalanx with a flap preserves bone length that supports the overlying nail.
- The volar V-Y advancement flap (**FIG 2**) is well suited for transverse and dorsal oblique fingertip injuries.
 - The V-Y flap can cover defects of up to 2 cm² and can be advanced 1 cm.
- The thenar flap (**FIG 3**) and cross-finger flap (**FIG 4**) provide coverage for volar oblique injuries. The thenar flap provides improved sensory recovery and has a less conspicuous donor site compared with the cross-finger flap but requires greater finger flexion for inset, which can cause joint stiffness, particularly in elderly patients. However, the lack of donor-site morbidity and predictable outcomes makes the thenar flap our first choice, if possible, over the cross-finger flap.
 - The cross-finger flap can be used for defects up to 1.5 × 2.5 cm in size.
 - The thenar flap can be designed to cover the entire pulp with a width of up to 2 cm.

FIG 3 • A. Proximally based thenar flap is elevated from distal to proximal. **B.** Narrow donor sites may be closed primarily. **C.** This is done prior to flap inset to the fingertip defect to facilitate suture placement.

Preoperative Planning

- The risks and benefits of flap coverage for fingertip injuries are discussed with the patient during their initial assessment and reviewed again prior to their surgery.
- Fingertip and/or the removal of exposed bone followed by secondary intention healing are discussed as alternative treatment options.

FIG 4 • A. The cross-finger flap is composed of skin and subcutaneous tissue from the dorsal middle phalanx of the adjacent finger. **B.** The flap donor site is closed with an FTSG.

- Benefits of flap coverage include preservation of finger length, provision of durable soft tissue coverage, and good aesthetic results.
- Drawbacks include the creation of a donor site, the possibility of flap failure, and the need for longer immobilization.
- Cross-finger and thenar flaps require the injured digit to be placed in flexion, which can lead to postoperative stiffness.
- These flaps are contraindicated in patients at high risk of joint contractures, eg, elderly patients with arthritis or Dupuytren disease.

- The thenar flap cannot be performed in patients without adequate passive metacarpophalangeal (MCP) and interphalangeal joint flexion.

Positioning

- The patient is positioned supine with the arm on a hand table.

Approach

- Loupe magnification is helpful.
- Incisions are planned prior to inflation of the tourniquet.
- Exposed bone is smoothed out with a rongeur. Minimal shortening is performed.
- Soft tissues are debrided of all nonviable and contaminated tissue. A healthy wound bed is established prior to flap reconstruction.
- The sterile nail matrix should be shortened 2 mm proximal to the tip of the distal phalanx to prevent a hook-nail deformity.⁷ A hook-nail deformity can occur when there is a lack of distal support for the sterile matrix.
- The neurovascular bundles and FDP tendon insertion are protected throughout.

TECHNIQUES

■ V-Y Advancement Flap

- The flap width is marked to match the defect width distally; proximally, it is tapered as a V.
 - The proximal flap edge is traditionally located at volar midline of the distal interphalangeal (DIP) joint crease; proximal extensions have been described (see **FIG 2**).⁸
- The injured finger is exsanguinated, and a finger tourniquet is placed.
- The flap is incised; dissection is performed through the dermis. Once the subcutaneous tissues are exposed, no further deep dissection is required; this prevents injury to the bilateral neurovascular structures (**TECH FIG 1A**).
- Distally, the fibrous septa are divided from the distal phalanx periosteum to permit flap advancement.
- The central undersurface of the flap must not be undermined to maintain flap vascularity.

- The flap is inset into the defect and sutured into place with 4-0 nonabsorbable monofilament suture. The flap is secured to the surrounding intact skin and nail. Tension is avoided at the tip of the finger to lessen the risk of a hook-nail deformity.⁹
- The donor site is closed longitudinally in V-Y fashion (**TECH FIG 1B**). Alternatively, the donor site can be left open to heal secondarily, particularly if flap tension is a concern.⁹
- The tourniquet is released and flap vascularity is assessed (**TECH FIG 1C**). Alternating sutures may be released to lessen tension on the flap; these open areas are left to heal by secondary intention.
- Antibiotic-impregnated gauze is placed over all incisions and covered with sterile gauze. A soft finger dressing is applied.
 - A light dressing can be applied daily until the incisions are healed.
- The sutures are removed 2 weeks postoperatively.
- Range-of-motion (ROM) exercises may be started on postoperative day 2 to prevent finger stiffness.

TECH FIG 1 • A. The V-Y advancement is designed with a distal width matching the width of the defect. Proximally, the flap is tapered to a V at the volar midline of the DIP joint crease. The dermis is incised, exposing the subcutaneous tissues below. **B.** The V-Y advancement flap is inset distally to the surrounding intact skin and nail. The donor site is closed proximally in a longitudinal V-Y fashion. **C.** The tourniquet is released, and the vascularity of the flap is assessed. Color, capillary refill, temperature, and turgor of the flap are examined.

■ Cross-Finger Flap

- A template of the defect is used to mark the flap dimensions on the dorsum

of the middle phalanx of the adjacent donor finger (**TECH FIG 2A**).

- The flap is pedicled on the side of the donor finger adjacent to the defect.
- The lateral extent of the flap can be marked as far as at the junction of the glabrous and nonglabrous skin for larger defects.
- The arm is exsanguinated and a tourniquet inflated.
- The flap is elevated sharply, just above the paratenon, beginning from the edge of the donor finger farthest from the injured finger (**TECH FIG 2B**). Cleland ligament is divided.
- The flap remains hinged to the side of the finger closest to the injured finger, along the midaxial line (**TECH FIG 2C**; see **FIG 4**).
- The injured finger is flexed, and the flap is secured to the flap using 4-0 nonabsorbable monofilament sutures (**TECH FIG 2D,E**).

TECH FIG 2 • A. The fingertip defect is marked on the dorsum of the middle phalanx of the adjacent donor finger using a template of the wound. The flap is hinged on the side of the donor finger closest to the defect. **B.** The flap is incised sharply and elevated in the loose areolar plane above the paratenon. **C.** The paratenon must be preserved to enable FTSG take at the flap donor site. **D,E.** Volar and oblique views, respectively, of a cross-finger flap from the middle finger after inset into the defect of the index finger. The patient also sustained an injury to the volar middle phalanx of the middle finger that was closed with an FTSG. **F,G.** A dressing change is performed 1 week postoperatively to assess the flap and flap donor site, respectively. The flap provides durable, padded soft tissue coverage for fingertip injuries.

- A full-thickness skin graft (FTSG) is applied to the flap donor site. The FTSG can be inconspicuously harvested from the groin, medial proximal forearm, or nonglabrous hypothenar skin.
- Antibiotic-impregnated gauze is applied to the affected digit and FTSG donor site and covered with sterile gauze. A bolster dressing is applied over the skin graft. A splint is applied to the injured finger and its adjacent donor finger, immobilizing the interphalangeal joints; the metacarpophalangeal (MCP) joints may be left free.
- One week after the first surgery, a dressing change is performed (**TECH FIG 2F,G**). The bolster dressing is removed from the FTSG. A protective splint is reapplied.
- Two weeks after the first surgery, the flap is divided. Immobilization is not typically required after the second surgery, and ROM exercises are started.

■ Thenar Flap

- The injured digit is flexed into the palm (**TECH FIG 3A**). Maximal flexion

of the MCP and DIP joints is preferred while minimizing proximal interphalangeal (PIP) joint flexion to decrease postoperative PIP stiffness.

- The flap is marked over the ulnar aspect of the thenar eminence using a template of the defect size (**TECH FIG 3B**).
- Ulnar flap design is preferred on the thenar eminence to facilitate primary closure of the donor site; skin tension is decreased by adducting the thumb. Furthermore, designing the flap radially over the thenar eminence places the radial neurovascular bundle of the thumb at risk of injury.
- The flap width and length are designed 1.5 times wider and longer, respectively, than the defect length to permit tension-free inset with restoration of the normal rounded contour of the fingertip.
- The flap is proximally or distally based, depending on the geometry of the defect.
- The arm is exsanguinated and a tourniquet inflated.
- The skin and subcutaneous tissues of the flap are sharply incised. The flap is elevated from distal to proximal in the subcutaneous tissue plane, above the level of the palmar fascia, at a depth that matches the defect (**TECH FIG 3C**).
- Once the flap is elevated, the flap donor site is closed longitudinally with 4-0 nonabsorbable monofilament sutures. The thumb is adducted to facilitate primary closure of the donor site.

TECH FIG 3 • A. The flap is designed over the thenar eminence where the finger meets the palm when flexed. Maximal MCP and DIP joint flexion are preferred rather than PIP flexion to enable the finger to meet the palmar skin. Contractures of the PIP joint are more problematic postoperatively compared to those of the MCP and DIP joints. **B.** A template, cut out of foil, Telfa (shown here), or otherwise can be used to design the flap based on the defect size. **C.** The flap is elevated from distal to proximal in the

subcutaneous plane. The palmar fascia is not violated. The finger is flexed to bring the defect to the flap site. **D,E.** Volar and oblique views, respectively, of the flap inset to the intact skin around the defect and the nail. **F.** The thenar flap is divided at its proximal base. The proximal flap edge is inset to the proximal volar edge of the defect with sutures. The thenar donor-site skin is closed.

- An FTSG can be used if the flap donor site is too large for primary closure.
- Next, the injured finger is flexed and the flap is inset over the defect (see **FIG 3**).
- 4-0 nonabsorbable monofilament sutures are used to secure the flap to the defect; absorbable sutures are at increased risk of breakage and subsequent flap dehiscence.
- Multiple sutures are used to decrease the chance of accidental fingertip avulsion from the flap site (**TECH FIG 3D,E**).
- Antibiotic-impregnated gauze is placed over all incisions and covered with sterile gauze. A well-padded splint is applied dorsally over the injured finger to prevent accidental avulsion of the fingertip from the thenar eminence.
- Two weeks postoperatively, the flap is divided, and if needed, more skin is removed from the thenar area to cover the entire fingertip that is buried within the thenar pocket.
- The divided flap edge is sutured to the edge of the fingertip defect, and the thenar skin is closed with 4-0 sutures; absorbable or nonabsorbable sutures may be used at this stage (**TECH FIG 3F**).
- Immobilization is not typically required after the second surgery, and ROM exercises are started.

PEARLS AND PITFALLS

Physical findings

- Carefully assess the flexion and extension of the DIP for patients with a fingertip injury. Associated mallet injury is common.

Technique	■ Handle flaps atraumatically. The blood supply for fingertip flaps is random from small local vessels. ■ Cross-finger flap: The cross-finger flap can be used for resurfacing of fingertip defects of all fingers. A thumb defect is the most difficult to inset using a flap from the index finger because of the pronated position of the thumb relative to the other digits of the hand. Defects of the ring finger are best resurfaced with a flap from the middle finger, rather than the shorter small finger, for adequate inset. A fingertip defect of the small finger requires minimal flexion of the small finger for inset to a flap from the ring finger. ■ Thenar flap: The thenar flap can be used for all fingers; positioning is easiest for the index and middle fingers and most difficult for the small finger. ■ Obtain hemostasis and close the skin while the tourniquet is down to prevent a hematoma to optimize flap and graft survival. ■ Assess flap tension in the operating room with the hand at rest and with passive range of motion. If surgery is performed with local anesthesia only, active range of motion can also be assessed. Splint the hand accordingly; avoid immobilization of uninvolved joints that do not cause undue tension on the reconstruction when moved.
Postoperative	■ Perform second-stage flap division 2 wk after flap inset. Longer periods of immobilization lead to worsening joint stiffness.
Therapy	■ Patients can follow a home therapy program for fingertip desensitization.

POSTOPERATIVE CARE

- Fingertip sensitivity is the most common patient complaint following fingertip injury and reconstruction. Cold sensitivity can be particularly troublesome.
 - Time, reassurance, and hand therapy are beneficial.
 - Massage, desensitization exercises, and cortical retraining of the finger are useful techniques.
- Fingertip protectors can be worn early in the postoperative period when the fingertip is most sensitive. They can be weaned over time as symptoms improve.

OUTCOMES

- V-Y advancement flap

- Excellent contour of the fingertip can be achieved (**FIG 5**).
- Near-normal sensation is restored.
- Cross-finger flap
 - Good aesthetic outcomes are achieved following fingertip reconstruction (**FIG 6A,B**).
 - Sensory recovery improves with time; protective sensation is recovered, but tactile gnosis is not.¹⁰
 - Despite difficulty with cortical relearning and incomplete sensory recovery, particularly in adult patients, patient satisfaction remains high.¹¹
 - The donor site is aesthetically unappealing (**FIG 6C**), particularly for female patients, and the flap color match may be poor, especially in dark-skinned patients.
 - A thenar flap is favored for female and dark-skinned patients rather than a cross-finger flap.
- Thenar flap
 - Donor-site tenderness can be problematic; early hand therapy is recommended.
 - Sensory recovery in the injured finger is typically better compared to a cross-finger flap.¹²
 - Aesthetic outcome of the reconstructed fingertip is excellent, and the donor site is hidden in the palm (**FIG 7**).

FIG 5 • The V-Y advancement flap of the index finger restores the contour of the fingertip with sensate,

durable soft tissue coverage. The donor site is inconspicuous. The incisions over the volar finger pulp can be sensitive; hand therapy may be required postoperatively.

COMPLICATIONS

- A shortened distal phalanx results in the loss of nail bed support. A hook-nail deformity can result. Excision of the sterile nail matrix 2 mm proximal to the shortened bone can help prevent this complication. The patient is taught to trim the nail frequently.
- If the nail remains troublesome, nail bed obliteration can be performed.
- A V-Y advancement flap creates additional incisions over the volar finger pulp. Hypertrophic and hypersensitive scarring can result.
- With regional flaps, stiffness can be marked postoperatively, particularly for older patients with arthritis and other comorbidities. Patients must be consulted preoperatively on the need for hand therapy following a two-stage flap reconstruction. For severe contractures, static progressive splinting can be used.

FIG 6 • The cross-finger flap provides excellent resurfacing for a fingertip injury, shown here volarly **(A)** and laterally **(B)** 4 months postoperatively. **C.** The appearance of the FTSG at the donor site, shown 4 months postoperatively, improves with time but remains noticeable over the dorsal middle phalanx of the donor finger. Aesthetic considerations must be discussed with the patient prior to use of this flap.

FIG 7 • The appearance of the reconstructed index fingertip and the thenar flap donor site 3 months postoperatively shows satisfactory healing.

- V-Y advancement and thenar flaps transfer glabrous skin to fingertip injuries; cross-finger flaps do not. Furthermore, cross-finger flaps may transfer hair-bearing skin to the volar skin pulp. Laser hair removal can be used once the flap is healed.

46 Flap Coverage of Thumb Defects

CHAPTER

Kate Elzinga and Kevin C. Chung

DEFINITION

- The thumb accounts for over 40% of hand function.¹ Maintenance of length, ideally beyond the neck of the proximal phalanx, is critical for stable pinch and grasp.
- The goals of thumb reconstruction include maximizing length, stability, strength, mobility, sensation, durability of coverage, and appearance while minimizing donor-site morbidity.
- The function of the thumb is optimized following injury by restoring a sensate thumb pulp.²

ANATOMY

- The volar thumb is covered by thick, durable, highly innervated, glabrous skin.
- Dorsally, the nail provides protection for the distal phalanx and counterpressure for the pulp during pinch.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Following a thumb injury, important patient factors include age, sex, handedness, comorbidities, medications, allergies, occupation and avocations, and smoking status.
- Injury factors to consider include the time and mechanism of injury, the degree of tissue contamination and necrosis, and any previous hand injuries.
- The patients' goals are explored. Their desire for a rapid return to work and their level of compliance and motivation are considered when formulating a reconstructive plan.
- The thumb wound is examined, noting the level of the injury and tissue loss

(skin, soft tissue, neurovascular bundles, tendons, bone, nail). Exposed structures are evaluated and documented.

- The thumb's color, capillary refill, turgor, and temperature are assessed as part of the vascular exam. The digital nerves are assessed using light touch, two-point discrimination, or the ten test.³
- The function of the extensor pollicis longus and that of the flexor pollicis longus (FPL) are tested by asking the patient to actively flex and extend the interphalangeal (IP) joint of the thumb.
 - A digital block can be used for patient comfort to facilitate the examination following sensory testing of the thumb.
- Donor sites are examined locally and regionally for thumb reconstruction.

IMAGING

- Plain radiographs are performed for the thumb to assess for bony injury, level of amputation, and presence of a foreign body.

NONOPERATIVE MANAGEMENT

- Small defects, up to 1 cm² without exposed bone or tendon, heal well by secondary intention.
 - Ingrowth of glabrous skin results in durable, sensate coverage.
 - Moist, antibacterial dressings are applied daily.
 - Range-of-motion exercises are performed throughout to prevent stiffness.
 - Once healed, early use of the thumb is encouraged to help with desensitization of the fingertip and return of function.
- Elevation of the injured upper extremity and gentle compression decrease edema at the thumb defect site, which expedites wound healing.

SURGICAL MANAGEMENT

- Larger skin and subcutaneous tissue defects, over 1 cm² without exposed tendon or bone, can be covered with a full-thickness skin graft (FTSG).
 - Rapid healing occurs, but FTSGs are less durable and have poorer sensory recovery compared with healing by secondary intention.
- When tendon or bone is exposed, coverage with local and regional flaps is necessary.
- To restore sensate, durable coverage over an exposed distal phalanx, flap reconstruction with a local Moberg flap can provide coverage for defects of 1.5 cm in length or up to 2.5 cm in length if a transverse proximal releasing

incision is used (**FIG 1**).

- Larger defects can be covered with regional flaps such as the first dorsal metacarpal artery (FDMA) flap (**FIG 2**) or the reverse homodigital flap (**FIG 3**) based on the dorsal radial collateral artery.
- The FDMA flap can be harvested up to 6×3 cm in size.
- The reverse dorsoradial homodigital flap has been described from 2×2 cm up to 5×4 cm in size.⁴

FIG 1 • The Moberg flap is designed over the volar thumb for coverage of distal thumb defects. **A–C.** Incisions are made at the midaxial line over the radial and ulnar digit up to the volar MCP joint crease. The radial and ulnar digital neurovascular bundles are elevated within the flap. The flap is elevated above the paratenon of the FPL and advanced distally. Flexion of the IP joint facilitates flap inset.

Approach

- The patient is positioned supine with the arm on a hand table.
- Loupe magnification facilitates flap dissection.
- The flap incisions are designed using a template of the defect prior to tourniquet inflation.
- A tourniquet is used for flap elevation to create a bloodless field that facilitates

exposure and decreases the risk of injury to the neurovascular structures supplying the flap.

- Following flap elevation, the tourniquet is released. Flap perfusion is assessed. Hemostasis is achieved prior to flap inset to prevent a hematoma that could result in flap compromise.

FIG 2 • The FDMA flap is elevated from the dorsal proximal phalanx of the index finger for coverage of thumb defects. **A,B.** The flap can be raised as an island flap, using a straight line, lazy S, or zigzag incision as shown here for elevation of the pedicle back to the flap pivot point, which is found just distal to the EPL tendon.

FIG 3 • A–C. The reverse dorsoradial homodigital flap is based on the anastomosis connection of the dorsal radial collateral artery and the palmar arteries of the thumb at the middle third of the thumb proximal phalanx. The flap is harvested as a distally based, reverse flap for coverage of distal thumb defects.

TECHNIQUES

■ Moberg Flap

- Incisions are designed over the midaxial lines of the ulnar and radial thumb, at the junction of the glabrous and nonglabrous skin (**TECH FIG 1A**; see **FIG 1**). Proximally, the flap is marked to the metacarpophalangeal (MCP) joint crease bilaterally. If further advance is necessary, the flap can be

extended proximal to the MCP, Burow triangles can be excised at the flap base bilaterally, or the flap can be advanced as a V-Y flap⁵ or as an island flap.⁶

- The ulnar and radial digital nerves and arteries are elevated within the flap, which maintains the blood supply to the flap as well as innervation (**TECH FIG 1B**). The dorsal blood supply of the thumb from the princeps pollicis artery permits safe flap elevation without compromising the thumb's perfusion.
- When used as an island flap, a transverse, proximal releasing incision is made over the proximal phalanx (PP), connecting the two midaxial incisions. The radial and ulnar neurovascular bundles are protected. This release is seldom necessary because the thumb interphalangeal (IP) joint can be flexed sufficiently for the flap to cover the tip of the distal phalanx.
- The flap is raised from distal to proximal, above the paratenon of the flexor pollicis longus (FPL). As dissection proceeds proximally, advancement of the flap can be tested until tension-free inset is achieved. At this point, proximal dissection ceases.
- The flap should not be advanced more than 2.5 cm to avoid traction on the neurovascular bundles. To achieve advancement of 2.5 cm, a transverse proximal releasing incision is required; the flap is then advanced as an island flap (**TECH FIG 1C,D**). Without a proximal releasing incision, the first dorsal metacarpal artery (FDMA) flap can be advanced 1.5 cm.
 - The donor site can be closed with a full-thickness skin graft (FTSG) (**TECH FIG 1E**).
- If needed, the thumb MCP and IP joints are flexed to facilitate flap inset over the distal thumb defect.
 - Rarely, a K-wire is used to maintain the flexed position of the IP joint (**TECH FIG 1F**).
 - For older patients with arthritis, limited flexion is recommended to prevent an IP joint flexion contracture.

TECH FIG 1 • A. Loss of soft tissue following a remote traumatic crush injury resulted in inadequate pulp coverage of the distal phalanx tuft and patient discomfort. A Moberg flap was designed to resurface the distal volar tip of the thumb. **B.** The ulnar and radial neurovascular bundles are elevated with the flap. The digital arteries and nerves provide perfusion and innervation to the flap. **C,D.** To permit advancement of a Moberg flap up to 2.5 cm distally, it is elevated as an island flap. A proximal transverse incision is used to connect the ulnar and radial midaxial incisions. **E.** The donor site is covered with an FTSG. **F.** A K-wire can be used to maintain IP joint flexion to facilitate flap inset to the distal thumb.

- The flap is inset using 4-0 nonabsorbable monofilament suture. The flap is secured to the intact skin surrounding the defect and to the nail.
- If used, the FTSG is secured with a bolster dressing. Antibacterial gauze is applied to the flap incisions followed by sterile gauze and a well-padded thumb spica splint.
- The splint can typically be discontinued 1 week postoperatively, and range-of-motion (ROM) exercises are started for the MCP joint. Two weeks postoperatively, if present, the K-wire can be removed and IP ROM is initiated.

■ First Dorsal Metacarpal Artery Flap (see FIG 2)

- Over the dorsal hand, distal to the anatomic snuffbox, the radial artery gives off three branches: the dorsal carpal arch (radial branch), the princeps pollicis (middle branch), and the FDMA (ulnar branch). After giving off the FDMA, the radial artery dives deep between the two heads of the first dorsal interosseous (DIO) and joins the deep palmar arch.
- The FDMA travels within or just above the fascia of the first DIO radial to the index finger metacarpal. A branch of the dorsal sensory branch of the

radial nerve travels with the FDMA.

- The FDMA flap provides innervated vascularized soft tissue coverage for large thumb or first web space defects (**TECH FIG 2A,B**).
- It is designed over the dorsal PP of the index finger. Typically, the flap is designed from the proximal interphalangeal joint to the MCP joint; proximal extensions are possible for coverage of larger defects (**TECH FIG 2C**).
- Ulnarly and radially, the flap extends to the midaxial lines of the index finger at the junction of the glabrous and nonglabrous skin.
- The pedicle is a proximal adipofascial extension of the flap that contains the FDMA, two dorsal veins, a branch of the dorsal sensory branch of the radial nerve, subcutaneous adipose tissue, and the fascia of the first DIO.
- Alternatively, the pedicle may be designed as a dermofascial flap extension with a 1-cm strip of overlying skin (**TECH FIG 2D**). In these cases, the skin donor-site defect from the pedicle harvest can be closed primarily.
- The pivot point of the flap is marked distal to the extensor pollicis longus at the junction of the metacarpal bases of the thumb and index finger. A handheld Doppler ultrasound (US) can be used to map the course of the FDMA from the dorsoradial index finger PP to the flap pivot point. The course of the FDMA is reliable; US mapping is optional.
- The flap is elevated above the paratenon of the extensor digitorum communis (EDC) and extensor indicis proprius (EIP). It is raised from distoulnar to proximoradial toward the pedicle that enters the flap base on the radial side of the index finger metacarpal.
- As the dissection approaches the proximoradial aspect of the flap and the first DIO is visualized proximal to the MCP joint, dissection must be continued deep to the fascia of the first DIO to prevent injury to the pedicle.
- When harvested as an island flap, a straight line, a lazy S, or a zigzag incision can be used from the flap base to the flap pivot point for pedicle exposure and elevation. The skin is incised and thin skin flaps are elevated radially and ulnarly in the subdermal plane. The pedicle is raised 1 cm in width. The subcutaneous fat and fascia are included to protect the FDMA and accompanying veins; the FDMA is not skeletonized.
- Our preferred approach is to harvest the flap with a dermofascial pedicle rather than as an island flap. A 1-cm skin bridge is incised. A wider adipofascial strip can be harvested below.

- Including the dermis helps protect the pedicle below during dissection and lessens the risk of pedicle kinking or compression during flap inset.
- The pedicle is raised with the flap from distal to proximal, just above the first DIO muscle (**TECH FIG 2E**).
- When harvested with skin overlying the pedicle, the flap is inset using a skin incision from the flap pivot point proximally to the thumb defect distally (**TECH FIG 2F**).
- When used as an island flap, the flap can be inset under a tunnel (**TECH FIG 2G**).
 - There is an increased risk of venous congestion of the flap when tunneled compared to inset using a skin bridge.
- Tension-free closure of the flap into the defect is performed using sutures (**TECH FIG 2H–J**).
- An FTSG is used to close the FDMA flap donor site (**TECH FIG 2K,L**). A bolster dressing is placed over the FTSG on the dorsal index finger PP.
- Antibacterial gauze and dry gauze are applied to the flap incisions.
- A well-padded splint is applied, taking care to avoid pressure on the flap or pedicle.
- The splint can typically be discontinued 1 week postoperatively, and ROM exercises are started as long as they do not cause undue tension on the flap.

A

B

C

D

E

F

TECH FIG 2 • A,B. A traumatic injury to the ulnar and volar thumb can be resurfaced using a FDMA flap. Prior to reconstruction, the wound should be free of infection and necrotic tissue. **C.** Most commonly, the FDMA flap is designed from the MCP proximally to the proximal interphalangeal joint distally over the dorsal index finger. Proximal extensions can be used as shown here for coverage of larger thumb defects. **D.** The FDMA flap can be raised with a dermofascial pedicle, as shown here, or with an adipofascial pedicle. The flap pivot point is marked here with an “X” at the junction of the first and second metacarpal bases, just distal to the EPL. An incision from the pivot point to the defect is marked for flap inset; alternately, the flap could be tunneled into the defect if an adipofascial pedicle was raised. **E.** The fascia of the first DIO is included with the pedicle to prevent injury to the FDMA and the draining veins of the flap. Here, the first DIO is shown radial to the flap pedicle, exposed but not violated. The paratenon is preserved over the extensor tendons of the index finger, shown ulnar to the flap pedicle. **F.** An incision is made from the flap pivot point to the thumb defect. The flap mobility is tested; tension-free inset is critical for flap survival. **G.** A different patient is shown here. In this case, the FDMA flap was raised with an adipofascial pedicle and tunneled into the defect. A wide tunnel is created to prevent pedicle compression and venous congestion. **H–J.** The FDMA flap and its dermofascial pedicle are inset using sutures. The nail had been avulsed; a splint was placed into the nail fold. The FDMA flap donor site was closed with an FTSG. **K,L.**

For this patient, the flap was tunneled into the defect over the volar-ulnar thumb and sutured into position. The flap donor site and additional superficial wounds over the distal radial index and middle fingers were closed with FTSGs.

■ Reverse Dorsoradial Homodigital Flap

- The reverse dorsoradial homodigital flap is harvested from the dorsoradial side of the thumb metacarpal (see **FIG 3**).
- Its arc of rotation permits coverage of distal volar and dorsal thumb defects and radial defects of the proximal and distal phalanx of the thumb.⁷ It is most commonly used for smaller defects over the dorsum of the thumb; the FDMA flap provides more tissue and is better suited for coverage of larger volar defects of the thumb.
- The flap pedicle is the dorsal radial collateral artery, which is a branch of the radial artery over the dorsoradial hand at the anatomic snuffbox. It passes under the extensor pollicis brevis (EPB) tendon as it travels from ulnar to radial. The pedicle is consistent in its course and caliber, traveling distally 1 cm radial to the midline of the dorsal thumb. It communicates with the palmar vessels at the middle third of the PP, permitting this flap to be used reliably as a reverse island flap.
- The course of the dorsal radial artery can be identified using a Doppler US. It runs from the snuffbox to the middle of the dorsoradial PP. The pivot point of the flap is over the middle of the dorsoradial PP.
- Using a template of the defect, the flap is designed over the dorsoradial thumb metacarpal, centered over the dorsal radial collateral artery.
- The skin island is incised, starting at its proximal edge. The dorsal radial collateral artery is identified, and the flap design is adjusted as needed to ensure it is over the pedicle.
 - The flap is raised above the paratenon of the extensor tendons. The incision over the distal flap is made through the dermis, but not deeper, to avoid transection of the pedicle below.
- The flap is elevated from proximal to distal. The dorsal radial collateral artery is divided just distal to where it passes under the EPB.

- A branch of the dorsal sensory branch of the radial nerve runs with the dorsal radial collateral artery. It is divided proximal to the flap to permit flap elevation. This sensory nerve branch can be coapted to the distal radial or ulnar digital nerve of the thumb; however, significant improvement in flap sensitivity has not been demonstrated.⁴
- A skin incision is made from the flap donor site to the defect to permit inset while minimizing the risk of pedicle compression and venous congestion that would occur if the flap were tunneled.
 - A lazy S or a zigzag incision is used.
 - Skin flaps are elevated subdermally radially and ulnarly from the flap donor site to the midpoint of the PP dorsally over the thumb.
- The pedicle is elevated with the surrounding subcutaneous tissue to ensure adequate venous outflow; all nearby venous skin branches are included in the flap elevation. The dorsal radial artery is not skeletonized.
- The flap is inset into the defect and sutured into place. The skin above the pedicle is loosely tackled together to prevent compression and left partially open to heal by secondary intention or covered with an FTSG.
- The flap donor site is closed primarily for flaps up to 4 cm in width. Larger donor sites are closed with an FTSG and covered with a bolster dressing.
- The flap incisions are covered with antibacterial gauze, sterile gauze, and a well-padded, hand-based thumb spica splint.
- The splint can be removed in one week and ROM exercises started.

PEARLS AND PITFALLS

Physical findings

- The anatomic course of the FDMA and dorsal radial collateral artery is consistent from the radial artery. Doppler US can be used as an adjunct during flap design, but it is not mandatory. Injuries to the dorsal radial hand and wrist preclude the use of these flaps as the flap pedicles may have been damaged. In these cases, an alternate flap should be used.

Technique

- The FDMA flap donor site leaves a visible donor site over the donor index finger. It can be harvested as an adipofascial flap to minimize the aesthetic morbidity of the donor site; however, the reconstruction of the thumb defect is compromised if the FDMA

flap requires an FTSG for coverage. A skin graft on the flap will be less durable and less sensate.

- Maintaining the paratenon over the tendons during flap harvest permits FTSG take at the donor site for an island Moberg flap, FDMA flap, and reverse dorsoradial homodigital flap. It also facilitates smooth tendon gliding for the FPL following a Moberg flap harvest, the EDC and EIP after a FDMA flap, and the EPL and EPB after a reverse dorsoradial homodigital flap.

Postoperative

- The most complete and natural sensation for the thumb pulp is regained using a Moberg flap. Over time, patients will adapt to the sensory input from the FDMA flap; however, cortical retraining is often incomplete and the patient continues to feel as though the dorsal index proximal phalanx is being touched rather than the pulp of the thumb. The homodigital island flap is not innervated. Sensation may be partially regained through the ingrowth of nearby cutaneous nerve fascicles.

Therapy

- Excessive IP joint flexion, particularly for over 2 weeks, can lead to a flexion contracture following an FDMA flap. Early ROM exercises are recommended, as long as flap viability is not compromised, to minimize IP joint stiffness.
- Hand therapy can help a patient regain ROM following a thumb injury. It can also help with desensitization of the reconstructed thumb and donor site.

FIG 4 • The FDMA flap provides excellent soft tissue coverage for thumb defects. The donor-site aesthetics improve with time. Here, the FDMA flap reconstruction is shown at 2 weeks (**A**) and 16 months (**B,C**) postoperatively.

POSTOPERATIVE CARE

- Nonabsorbable sutures are removed 2 weeks postoperatively.
- The dressings are changed and any FTSG bolster dressings are removed 5 days postoperatively.
- ROM exercises are started 5 to 7 days postoperatively.
- If there is any concern of flap tension, a thermoplastic splint can be used to protect the flap for an additional 1 to 2 weeks between ROM exercises and during sleep.

OUTCOMES

- The Moberg flap best restores sensation to thumb defects. The reverse dorsoradial homodigital flap is not innervated and offers the least complete sensory recovery, averaging 10-mm two-point discrimination.⁴
- The Moberg, FDMA, and homodigital flaps restore the thumb pulp contour well (**FIG 4**).
- The Moberg flap has the least donor site morbidity but can be used only for coverage of smaller thumb defects. The FDMA and homodigital flaps permit coverage of larger defects; the patient must be counseled preoperatively about the visible donor sites on the dorsal hand.

COMPLICATIONS

- Hair growth is rare over the dorsoradial thumb metacarpal. The Moberg and reverse dorsoradial homodigital flaps provide hairless coverage for thumb defects. In contrast, the FDMA flap typically contains hair. Laser hair removal can be used once the flap has healed if hair growth is problematic.

47 Reverse Flow Radial Forearm Flap

CHAPTER

Kate Elzinga and Kevin C. Chung

DEFINITION

- The most commonly used regional flap for coverage of volar and dorsal hand and wrist wounds is the reverse radial forearm flap (RRFF). It is a reliable and versatile flap.
- The radial forearm flap can be used as an antegrade flap to cover defects of the elbow.
- The radial forearm flap can also be harvested as a free flap for distant defects.
- The RRFF can be designed up to 35×15 cm in size, harvesting up to two-thirds of the circumference of the forearm, from 4 cm distal to the antecubital fossa to the wrist crease.
- The RRFF's large size makes it suitable for coverage of nearly all wrist and hand wounds. However, the arc of rotation of the flap into the defect typically precludes harvesting the flap extending to the distal forearm.
- The flap can be pre-expanded to further increase its dimensions proximally in the forearm for adequate use as a reverse flap, although this is rarely necessary.¹

ANATOMY

- The RRFF is a Mathes and Nahai type B flap; it is supplied by septocutaneous perforators. Its pedicle is the radial artery and its two accompanying vena comitantes. The radial artery is divided proximally. Retrograde flow occurs from the ulnar artery through the deep palmar arch into the radial artery to provide arterial inflow to the flap.
- The radial artery originates from the brachial artery. It travels under the brachioradialis (BR) for most of its course. Distally, it is found in the interval

between the BR radially and the flexor carpi radialis (FCR) ulnarly. The radial artery perforators travel within the septum between the BR and FCR to supply the overlying fascia and skin (**FIG 1**).

- There are 6 to 10 septocutaneous perforators arising from the radial artery 2 cm proximal to the radial styloid.² A reverse radial artery perforator flap can be elevated on these perforators to preserve the radial artery for patients without an intact palmar arch.^{3,4}
- The cephalic vein can be harvested with the RRFF although it does not play a role in the venous drainage of reverse flaps. Venous outflow is through the avalvular oscillating veins.⁵ In cases of venous congestion, anastomosis of the cephalic vein within the flap will decompress the venous congestion.
- The RRFF is designed over the proximal and middle volar forearm.
- The RRFF can be harvested as a fasciocutaneous, adipofascial, or fascia-only flap. It may also be raised above the fascia; the subcutaneous tissue and dermis above the fascia are raised suprafascially.

FIG 1 • The radial artery and its vena comitantes are found in the distal forearm within the intermuscular septum between the BR radially and the FCR ulnarly. The radial border of the RRFF can be centered over the radial artery as shown here. Alternatively, the flap can be designed with its radial margin over the radial artery. The LABC and cephalic vein are optional structures that can be included in the flap design.

- The lateral antebrachial cutaneous nerve (LABC) can be harvested with the flap and coapted to a sensory nerve at the defect site to innervate the flap.
- Alternatively, the LABC can be left in situ during flap harvest, preserving the sensation to the radial forearm.⁶
- The palmaris longus can be elevated with the flap for use as a vascularized tendon graft. For example, it can be used for an extensor tendon defect or to create a flexor pollicis longus during osteoplastic thumb reconstruction with an iliac crest bone graft and a RRFF.⁷ The BR can also be included as a vascularized tendon graft or part of the radius as a vascularized bone graft.⁸
- The pivot point for the RRFF is the radial styloid.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient is assessed for suitability for regional flap reconstruction following a wrist or hand injury.
- Important history includes the patient's age, handedness, and occupation and avocations.
- The patient's past medical history, medications, allergies, and social history are noted. In particular, risk factors for flap loss, poor wound healing, and additional postoperative complications are discussed.
- Comorbidities associated with poor wound healing include smoking, diabetes mellitus, end-stage renal disease, cardiac disease, peripheral vascular disease, vasculitis, malnutrition, immunosuppression, and hypercoagulable states.
- Details of previous trauma or surgeries to the forearm are gathered. History of any previous radial artery cannulation for invasive blood pressure monitoring is also important.

- If there is concern of damage to the radial artery or its perforators, angiography can be performed to evaluate the vascularity of the arm.
- The patient's defect is examined. The size of the wound is measured. Exposed structures, necrotic tissues, and any signs of infection are documented.
- Wounds with exposed tendon and bone are best covered using flaps. The radial forearm flap is a pedicled regional flap that can be safely performed in most patients. It alleviates the need for a two-stage flap reconstruction such as a groin flap or microvascular reconstruction with a free flap.
- The vascularity of the hand must be carefully assessed. If the radial artery is harvested for the RRFF, the patient must have an intact palmar arch with arterial inflow from the ulnar artery to prevent hand and finger ischemia.
- The modified Allen test is used to clinically assess the integrity of the palmar arch (**FIG 2**). The examiner compresses the patient's ulnar and radial arteries at the volar wrist and then instructs the patient to open and close the hand into a tight fist until the palm is blanched. The examiner then releases the ulnar artery and looks for arterial flow from the ulnar artery through the palmar arch to the radial side of the hand within 6 seconds. The test is repeated to assess the radial artery.
- The motor and sensory nerves of the hand and forearm are tested. Any pre-existing abnormalities are noted.

IMAGING

- Plain radiographs are performed for patients with traumatic wounds. Any fractures, foreign bodies, and abnormal joint intervals secondary to ligamentous injuries are noted.
- The authors do not routinely perform angiography prior to RRFF harvest. If the patient has sustained previous trauma to the forearm or has undergone previous surgery to the forearm, angiography can be used to evaluate the integrity of the vascular system of the arm and the patency of the radial artery, ulnar artery, and palmar arch.
- An ultrasound (US) can be performed to do a Doppler Allen test if the patient is unable to participate in a clinical Allen test or to confirm clinical findings.⁹ This is not necessary for most patients.

NONOPERATIVE MANAGEMENT

- Prior to flap coverage, the wound is debrided to ensure it is clean with no necrotic tissue.

- Antimicrobial dressings are used prior to RRFF coverage to minimize the bacterial load of the wound.

SURGICAL MANAGEMENT

- The size of the patient's wound and the presence of exposed bone and tendon help to guide the selection of an appropriate flap for reconstruction.
- Local flaps can be used for small defects.
- Regional flaps, such as the RRFF, are excellent options for moderate- to large-sized defects of the volar and dorsal hand and fingers.
- Free flaps are an alternative but require a longer operative time, a distant donor site, and microsurgical expertise.

Preoperative Planning

- The risks and benefits of flap reconstruction are discussed in detail with the patient.
- The benefits of the RRFF include a supple, durable, and thin flap for reconstruction. The color match is excellent for dorsal hand defects. In dark-skinned patients, the color match for volar defects may be poor.
- The risk of partial or complete flap loss is discussed.

FIG 3 • The RRFF is harvested over the proximal and/or middle third of the forearm, depending on the required size and arc of rotation. For RRFFs harvested with a width over 6 cm, closure with an STSG is required.

- The patient is counseled about the donor-site defect of the RRFF. The donor site is visible over the proximal volar forearm.
- For flaps over 6 cm in width, a split-thickness skin graft (STSG) is typically used to close the donor site (**FIG 3**).
- The appearance of the STSG at the recipient site, the appearance of the STSG donor site (typically the anterior upper thigh), and the risk of the STSG failure are explained to the patient.
- If the LABC is harvested, the patient must be counseled about the sensory loss he or she will experience over the radial forearm postoperatively. This may improve with time due to collateral sprouting of adjacent nerves, but full sensory recovery is unlikely.
- The most feared complication of RRFF harvest is ischemia of the hand following division of the radial artery. If this occurs, a vein graft is typically used to restore the radial artery and thus the arterial inflow of the hand. The patient is counseled about this rare complication and the need for possible vein graft harvest, either the cephalic vein or the saphenous vein.

Positioning

- The patient is positioned supine with the arm supinated on a hand table for RRFF harvest.
- A tourniquet is applied over the upper arm.
 - After the flap incisions are designed, the tourniquet is inflated to permit safe flap elevation in a bloodless field.
 - Once the flap has been elevated with its pedicle, the tourniquet is deflated and the vascularity of the flap and the hand are assessed. Hemostasis is achieved prior to flap inset and donor-site closure to minimize the chance of hematoma and subsequent flap compromise.

Approach

- The flap is typically designed over the middle third of the volar forearm using a template of the wound to mark the flap dimensions. The arc of rotation of the

flap is tested to ensure the inset will be tension-free. If the flap must reach further distally, it can be designed over the proximal third of the forearm.

- Loupes are worn to facilitate flap elevation.

TECHNIQUES

■ Reverse Flow Radial Forearm Flap

- The flap can be designed with its radial margin over the radial artery or centered over the radial artery (**TECH FIG 1A–C**).
 - When centered over the radial artery, the flap is harvested around the radial border of the forearm that results in a more visible donor site.
- The radial artery can be palpated over the volar, radial wrist in the interval between the FCR and BR tendons, and then followed proximally using a Doppler US. The course of the radial artery is marked, starting from the volar, radial wrist to the middle of the antecubital fossa.
- An incision is designed from the distal margin of the flap skin paddle to the flap pivot point at the radial styloid. This permits elevation of the pedicle and rotation of the flap distally into the defect.
- When designed as a fasciocutaneous flap, the RRFF skin paddle is marked over the proximal and middle forearm. When used as an adipofascial or fascial flap, an incision is made over the radial proximal forearm centered over the radial artery. Thin skin flaps are lifted radially and ulnarly to expose the adipofascial tissue below.
- The RRFF is raised from ulnar to radial to the FCR and from radial to ulnar to the BR.
- The flap is elevated in either the suprafascial or the subfascial plane, depending on the tissues required for reconstruction of the defect. For both flap types, the fascia must be incised and harvested with the flap radially over the BR and ulnarly over the FCR to include the pedicle (**TECH FIG 1D**); the flap cannot be raised entirely in the suprafascial plane.

TECH FIG 1 • A. This patient presented with a first web space adduction contracture secondary to long-standing thumb carpometacarpal joint osteoarthritis. To alleviate the patient's basilar joint pain and to restore her first web space, a trapeziectomy was planned along with pinning of the first metacarpal in an abducted position and first web space contracture release with interposition of a RRFF. **B.** The surgical incisions are marked. A longitudinal incision was marked over the first web space, extending from the dorsal to the volar surface of the hand to permit the release of the contracted skin, subcutaneous tissues,

and adductor pollicis. The metacarpophalangeal joint of the thumb was marked as a reference point. The carpometacarpal joint of the thumb was marked proximally; this incision was used for the trapeziectomy. **C.** An RRFF was designed using a template of the first web space defect site. A 6 cm long × 4 cm wide flap was marked over the middle of the volar forearm, centered over the radial artery. The radial artery can be palpated distally between the FCR and BR and followed proximally using a Doppler US. Its course is marked by the dotted line. The radial styloid is the flap pivot point. **D.** The fascia must be raised over the BR radially and over the FCR ulnarly to ensure that the radial artery and its vena comitantes are raised with the flap. The LABC and cephalic vein can be included in the flap design if desired. **E.** Prior to tunneling the flap through a wide subcutaneous tunnel over the dorsoradial wrist to the first web space, the arc of rotation of the flap is tested to ensure the flap reaches the first web space defect without tension on it or its pedicle. Care is taken to avoid kinking and compression of the pedicle during inset. The tendons of the BR and the FCR are visible at the flap donor site. **F.** RRFFs less than 6 cm in width can be closed primarily, as shown here. Wider flap donor sites are closed with a STSG. In this case, the RRFF was tunneled distally into the first web space defect. Alternatively, a skin incision can be used to allow flap rotation distally. A percutaneous pin is placed to maintain thumb metacarpal abduction following first web space contracture release for 4 weeks.

- Perforators from the radial artery to the overlying fascia and skin are

identified in the lateral intermuscular septum between the BR and the FCR and are protected. To facilitate the identification of the lateral intermuscular septum, particularly in the proximal arm, the BR is retracted radially and the FCR is retracted ulnarly.

- The paratenon is preserved over all tendons during dissection; this permits STSG take when a wide flap is harvested. The superficial sensory branch of the radial nerve is protected throughout.
- The flap's proximal margin is incised. The radial artery and its vena comitantes are identified and ligated. Microclips or sutures can be used.
- If the LABC is harvested with the flap, it is divided at the proximal flap margin. If it is left in situ, it is identified and protected throughout the dissection as flap elevation continues.
- The dermis of the distal margin of the flap is incised sharply, taking care not to penetrate into the soft tissues below to prevent injury to the radial artery and vena comitantes.
- The skin incision is made from the distal flap margin to the flap pivot point. The flap is elevated from proximal to distal with its pedicle. The pedicle includes the radial artery and its vena comitantes as well as the cephalic vein and LABC when desired.
- When a fasciocutaneous flap is raised, the RRFF skin is secured to the underlying fascia using absorbable sutures to prevent shearing of the cutaneous perforators.
- Vascular branches from the radial artery to the flexor pollicis longus and to the radius are divided using microclips and bipolar cautery to permit pedicle elevation to proceed distally.
- The flap is inset into the defect site using sutures.
 - The flap can be inset through a wide tunnel (**TECH FIG 1E**) or using a skin incision from the flap pivot point at the radial styloid to the defect.
 - Care is taken to avoid kinking or compression of the pedicle and any flap tension.
- The RRFF donor site is closed primarily if the flap is adipofascial, fascial, or a narrow fasciocutaneous flap (**TECH FIG 1F**). Donor-site skin defects over 6 cm in width are closed with a STSG; a sheet STSG is preferred over a meshed STSG for improved appearance.
- The skin incision between the flap donor site to the radial styloid is closed primarily following pedicle dissection in this area.

- The flap vascularity is assessed after closure of all incisions. Color, capillary refill, temperature, and turgor are noted.

FIG 2 • The modified Allen test is used to confirm retrograde flow into the radial artery from the ulnar artery across the palmar arch prior to division of the radial artery for a RRFF. If the palmar arch is not patent, a reverse radial artery *perforator* flap or alternate flap should be used instead.

- The vascularity of the hand is confirmed, and arterial inflow to all digits is documented.
- Antibiotic-impregnated gauze is applied to all incisions and covered with sterile gauze. The skin paddle of the flap is left visible to facilitate postoperative flap checks.
- If used, the STSG is carefully padded to prevent shear and to optimize take.
- A well-padded forearm splint is applied.
- The arm is elevated postoperatively to minimize edema.

PEARLS AND PITFALLS

Physical findings	■ Previous trauma to the volar radial forearm precludes the use of the RRFF. In these cases, the small perforators to the overlying fascia and skin may have been injured.
Technique	■ For patients with recurrent or persistent carpal tunnel syndrome, an adipofascial RRFF can be used to wrap the median nerve. ¹⁰
Postoperative	■ No anticoagulation is used for pedicled flaps. Prophylactic low molecular weight heparin injections are given daily to prevent deep vein thrombosis until the patient is mobilizing well postoperatively. ■ A Doppler US can be used after flap inset to identify audible arterial and venous perforators to the skin paddle. The location of these perforators can be marked with a 6-0 polypropylene suture. This is not critical for pedicled flaps, but can be a helpful adjunct for postoperative monitoring.
Therapy	■ Scar massage and desensitization exercises can be started under the guidance of a hand therapist once the incisions are healed, approximately 3 weeks postoperatively.

POSTOPERATIVE CARE

- Flap checks are performed every 2 hours postoperatively. The flap and hand are assessed. If there is a lack of arterial inflow or venous outflow noted for the flap, the patient is taken back to the operating room urgently for flap exploration. A kink in the pedicle, hematoma, or compression from a tight closure can result in flap compromise.
- The patient is discharged home on postoperative day 3.
- The patient returns to the clinic on postoperative day 5 for a wound check and dressing change. If an STSG was used, its take over the donor site is assessed.
- Early range-of-motion (ROM) exercises are performed for all uninvolved joints of the upper extremity. If the flap crosses the wrist, gentle wrist ROM exercises are initiated on postoperative day 5 to 7 as long as no flap compromise occurs.
- For flaps crossing the wrist, a resting wrist splint is worn to maintain the wrist in neutral alignment to 20 degrees of extension for 2 weeks postoperatively.

The splint is removed multiple times during the day for ROM exercises during the 2nd postoperative week. After 2 weeks, the splint is weaned.

OUTCOMES

- The fasciocutaneous RRFF provides excellent resurfacing for palmar defects. Adipofascial or fascia-only RRFFs with STSG coverage provide a thin reconstruction for the thinner dorsal skin of the hand; these flaps are less durable but minimize donor-site morbidity compared to fasciocutaneous RRFFs.
- The RRFF can be harvested with the LABC. This is particularly helpful for thumb reconstruction. The LABC is coapted to a digital nerve of the thumb to innervate the flap. Static two-point discrimination has been reported as 11 mm for these patients.⁷ If the RRFF is used for wrist coverage, the LABC can be coapted to a branch of the superficial sensory branch of the radial nerve.⁵

COMPLICATIONS

- Flap loss is unusual with a pedicled RRFF.
- If the patient is bothered by the appearance of the RRFF donor site over the proximal arm following closure with an STSG, serial excision of the STSG can be performed.

CHAPTER Ulnar Artery Perforator Flap

Kate Elzinga and Kevin C. Chung

DEFINITION

- The ulnar artery perforator flap was first described by Becker as a pedicled flap based on the dorsal branch of the ulnar artery (**FIG 1**).¹ The mobility of this flap is limited by its short pedicle.
- The ulnar artery perforator flap can also be designed based on the ascending branch of the dorsal branch of the ulnar artery, increasing its reach to distal hand defects (**FIG 2**).²
- The ulnar artery perforator flap is most commonly used as a pedicled flap. Alternatively, it can be harvested as a free flap.
- A major advantage of perforator flaps is the preservation of the major vessels of the forearm; the ulnar and radial arteries are not sacrificed.
- The ulnar artery perforator flap can be used for coverage of defects of the ulnar hand and wrist, both dorsal and volar, typically up to 10 × 5 cm in size.¹
 - Larger flaps, up to 20 × 9 cm, can be harvested, but venous congestion can result.³
 - Supercharging a larger flap by anastomosing a subcutaneous flap vein to a nearby vein of the dorsal hand can improve venous outflow.⁴
- The flap can be raised as a fasciocutaneous or adipofascial flap.

FIG 1 • The ulnar artery perforator flap is shown here based on the dorsal branch of the ulnar artery. It can be used for coverage of defects over the ulnar dorsal and volar wrist and hand (*shaded area*).

ANATOMY

- The hand is supplied by the radial and ulnar arteries that branch from the brachial artery over the antecubital fossa, 1 cm distal to the elbow joint. The ulnar artery travels distally beneath the flexor carpi ulnaris (FCU), volar to the flexor digitorum profundus. Perforators from the ulnar artery travel to the overlying fascia and skin between the FCU and the flexor digitorum superficialis. The superficial and deep palmar arches are located in the palm, formed by the radial and ulnar arteries.
- Sacrifice of the radial or ulnar artery for flap elevation risks hand ischemia if the patient does not have an intact palmar arch. Perforator flaps may be safely used in these cases.

- The ulnar artery gives off seven $\pm$ two perforators to the skin over the ulnar forearm with a diameter of 0.5 mm or greater.⁵
 - The pedicle length for propeller or free flaps based on these perforators is 3.3 mm on average, ranging from 2.5 to 4.0 mm.⁵
- About 69% of the perforators of the ulnar artery are musculocutaneous, traveling through the FCU or flexor digitorum superficialis to reach the skin.⁵
 - The remaining perforators are septocutaneous.
- The ulnar artery perforator flap can be designed as a propeller flap based on the dorsal branch of the ulnar artery. It can be harvested up to 15 cm in length, to the mid-forearm, depending on the location of the perforator.
- Greater pedicle length can be obtained when the flap is based on the ascending branch of the dorsal branch of the ulnar artery.

FIG 2 • The ulnar artery perforator flap has a longer pedicle and a greater arc of rotation when based on the ascending branch of the dorsal branch of the ulnar artery. The ascending branch travels proximally to the medial epicondyle. It supplies the overlying fascia and skin along its course.

- The dorsal branch of the ulnar artery arises from the ulnar artery 2 to 5 cm proximal to the pisiform.⁶

- Infrequently, in 2 of 26 cadaver dissections, the dorsal branch arises from the anterior interosseous artery rather than from the ulnar artery.⁷
- The dorsal branch of the ulnar artery has a diameter of 1.0 to 1.3 mm.² It travels from the volar distal forearm from radial to ulnar, under the FCU, to give off three branches:
 - The proximal branch enters the FCU 4 to 6 cm proximal to the pisiform.
 - The distal branch supplies the pisiform. It is called the pisiform artery.
 - The middle branch divides into an ascending and a descending branch over the dorsoulnar forearm to supply the forearm and hand, respectively. The ascending branch travels proximally to the medial epicondyle. The descending branch joins the dorsal carpal arch over the dorsal hand. An ulnar artery perforator flap can be designed based on the ascending branch of the dorsal branch of the ulnar artery and its two vena comitantes.²
- The ulnar artery perforator flap can be designed from the palmaris longus tendon volarly to the extensor digitorum communis tendon of the fourth finger dorsally.⁸
- The ulnar artery perforator flap is approximately 3 mm thick, providing thin soft tissue coverage.⁵
- The ulnar artery perforator flap is designed along the flap axis between the medial epicondyle and the pisiform (**FIG 3**). Proximally, the perforators are larger and more consistent and primary donor-site closure is easier.
 - When used as a free flap, the ulnar artery perforator flap is typically designed over the proximal forearm.
- The dorsal sensory branch of the ulnar nerve passes beneath the FCU 5 to 8 cm proximal to the pisiform to travel to the dorsal forearm. It is protected during dissection of the dorsal branch of the ulnar artery.
- Flaps widths up to 6 cm can be closed primarily over the ulnar forearm. Wider flaps require closure with a split-thickness skin graft (STSG).
- Bone defects of the small finger metacarpal can be reconstructed by harvesting vascularized cortical bone of the ulna with the ulnar artery perforator flap.⁹
 - Bone is harvested from the ulna 10 to 15 cm proximal to the pisiform between the FCU and extensor carpi ulnaris (**FIG 4**).

FIG 3 • To design an ulnar artery perforator flap, the medial epicondyle, pisiform, and FCU are marked. Next, the axis of the ulnar artery perforator flap is marked from the medial epicondyle to the pisiform. Ulnar artery perforators are identified along this line using a Doppler ultrasound. The flap is designed to include as many audible perforators as possible.

FIG 4 • The ulnar artery perforator flap can be used as an osteocutaneous flap for reconstruction of bone defects of the small finger metacarpal. Cortical bone of the ulna can be harvested in the flap 10 to 15 cm

proximal to the pisiform, between the flexor carpi ulnaris and the extensor carpi ulnaris. The flap is elevated on the ascending branch of the dorsal branch of the ulnar artery.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Important factors from the patient's history include the patient's age, sex, hand dominance, occupation and avocations, past medical history, medications, allergies, and social history.
- The timing and mechanism of the patient's injury are recorded. Traumatic injuries result from sharp, crush, and burn mechanisms. Oncologic defects result from sharp tissue resection.
- The patient's wound is explored, noting the size of the wound, contamination and tissue necrosis, and signs of infections.
 - Exposed structures are documented, in particular tendon and bone devoid of paratenon and periosteum; in these cases, flap coverage is required, graft take will not occur.
- Donor sites are assessed during wound reconstruction planning. Forearm local and regional flap donor sites are examined.
- Injuries to ulnar forearm preclude the use of the ulnar artery perforator flap. Ulna fractures often result in damage to the perforators, along with lacerations and crush injuries.

IMAGING

- Plain radiographs are used to assess for fractures, dislocations, and foreign bodies.
- Angiography is not typically performed unless there are specific concerns of the patency of the ulnar artery and its perforators.

NONOPERATIVE MANAGEMENT

- Prior to flap coverage, wound debridement is performed to prepare the wound bed for closure.
- Antibacterial dressings can be used prior to flap closure to decrease the wound's bacterial load.

SURGICAL MANAGEMENT

- The pedicled ulnar artery perforator flap is used for closure of ulnar wrist and hand defects.
- It has a smaller arc of rotation than does the radial artery forearm flap.
- It cannot reach the fingers.

FIG 5 • A. An ulnar artery *digital* perforator flap can be raised over the ulnar hand. The largest perforators are found near the metacarpophalangeal joint. **B.** The flap can be rotated distally up to 180 degrees to cover defects of the small finger and volar and dorsal distal hand.

- The ulnar artery perforator flap can be raised as a free flap to cover a variety of defects, including finger injuries. Sizes of 3.5×2 cm to 24×4 cm have been reported.⁵
- To cover finger injuries, the flap's arterial pedicle can be anastomosed to the digital arteries and the vena comitantes can be anastomosed to superficial dorsal veins of the finger.
- The medial antebrachial cutaneous (MABC) nerve of the forearm can be harvested with the flap and coapted to a digital nerve for sensate flap reconstruction.

- For injuries of the small finger or distal dorsal or volar hand, an ulnar *digital* artery perforator flap can be elevated from the ulnar aspect of the hand and rotated distally as a propeller flap for closure (**FIG 5**).
- Three or four perforators arise over the palmar aspect of the hypothenar eminence over the abductor digiti minimi from the ulnar artery to supply this flap.¹⁰ The largest perforators are found near the metacarpophalangeal joint. The flap can be raised as a subfascial or suprafascial flap.

Preoperative Planning

- The patient is counseled about flap reconstruction using the ulnar artery perforator flap. Benefits include thin, supple soft tissue coverage. The flap is durable and reliable.
- Risks included partial or complete flap loss, wound dehiscence, sensitive scars, and a visible donor site over the ulnar volar forearm.
- To permit ulnar artery perforator flap elevation, the dorsal sensory branch of the ulnar nerve must be divided in some cases. The dorsal sensory branch of the ulnar nerve branches from the ulnar nerve 5 to 8 cm proximal to the pisiform.
- Patients are counseled about the risk of sensory loss over the dorsal ulnar hand if the nerve is divided during flap elevation.
- Primary nerve repair should be performed to aid sensory recovery and to prevent a painful neuroma.

Positioning

- The patient is positioned supine with the arm out on a hand table.
- A tourniquet is placed on the upper arm.

Approach

- Loupes facilitate safe elevation of the flap and pedicle.
 - The ulnar artery can be palpated over the volar ulnar wrist. Ulnar artery perforators can be identified using a Doppler ultrasound.
 - The flap design is marked to maximize inclusion of audible perforators.
 - Incisions are planned prior to inflation of the tourniquet. The tourniquet is inflated during flap elevation to permit bloodless dissection. Once the flap and its pedicle are raised, the tourniquet is deflated to assess the flap's vascularity. Hemostasis is achieved prior to flap inset and closure.
-

TECHNIQUES

■ Ulnar Artery Perforator Flap

- The medial epicondyle, pisiform, and flexor carpi ulnaris (FCU) are marked. The axis of the flap is marked from the medial epicondyle to the pisiform, ulnar to the FCU. The approximate position of the dorsal branch of the ulnar artery is marked 4 cm proximal to the pisiform, ulnar to the FCU.
- The ulnar artery is palpated over the distal volar forearm. It is followed proximally using a Doppler ultrasound to identify and mark perforators of the ulnar artery on the overlying skin. The largest and most constant perforators are found over the volar ulnar forearm, at the junction of the proximal and middle third of the forearm.⁵ Perforators are also consistently found at the junction of the middle and distal thirds of the forearm.
- A template of the defect is used to mark the flap dimensions.

Pedicled Flap

- The flap is designed over the junction of the proximal and middle thirds of the forearm, including as many perforators as possible from the ascending branch of the dorsal branch of the ulnar artery.
- The flap is incised proximally and elevated from proximal to distal in a subfascial plane. It can be raised as a fasciocutaneous or adipofascial flap.
- The skin between the flap and the pivot point is incised using a lazy S-shaped incision. Thin skins flaps are lifted radially and ulnarly exposing the subcutaneous tissue below containing the dorsal branch of the ulnar artery and its accompanying veins. The pedicle is raised with a 4-cm-wide strip of adipofascial tissue to prevent injury to the pedicle. The flap and pedicle are raised from proximal to distal until the dorsal branch of the ulnar artery is seen entering the undersurface of the pedicle. This marks the pivot point of the flap, 4 cm proximal to the pisiform.¹¹
- The flap is tunneled into the defect, or a skin bridge is incised between the flap pivot point and the defect for flap inset.
- The flap donor site is closed primarily for fasciocutaneous flaps with a width less than 6 cm or using a STSG if wider. The STSG is typically harvested from the ipsilateral anterior thigh.

- Adipofascial flaps require coverage with a STSG after inset. Their donor sites can be closed primarily.
- Antibiotic-impregnated gauze and sterile dry gauze are placed over all incisions. The flap is left uncovered to facilitate.
- Postoperative flap monitoring. A well-padded splint is applied. Pressure on the flap is avoided.

Propeller Flap

- When used as a distally based propeller flap for hand and wrist coverage, the flap is designed over one dominant perforator from the dorsal branch of the ulnar artery; including additional perforators can prevent adequate rotation of the flap.
 - The largest caliber perforator or the most optimally located perforator is used.
 - Distal perforators facilitate flap rotation distally and thus are often selected when multiple perforators are available.
 - All perforators are preserved during initial flap dissection. The desired perforator is selected. All additional perforators are clamped to ensure that flap vascularity will be maintained based on the main perforator prior their division.
- The width of the flap is designed to match that of the defect (**TECH FIG 1A**).
- The length of flap is designed so that the distance between the perforator and the distal edge of the defect matches the distance between the perforator and the proximal edge of the flap.
- The skin distal to the flap is incised to confirm the location of the ulnar artery and its perforators prior to elevation of the flap. The skin is incised radial to the FCU.
 - The FCU is retracted ulnarly, exposing the ulnar artery and nerve below.
 - The perforators of the ulnar artery are identified and followed to the overlying skin to confirm that the flap is properly centered over the perforators.
- The flap is elevated subfascially from ulnar to radial to the radial border of FCU.
- The radial aspect of the flap is then incised.
 - The flap is elevated in a subfascial plane from radial to ulnar to the ulnar aspect of FCU, where the dorsal branch of the ulnar artery is seen entering

the flap.

- The basilic vein is typically elevated with the flap. The basilic vein can be followed 2 or 3 cm proximal to the proximal flap edge and harvested to permit venous supercharging if poor venous outflow is noted after inset.⁴
- The MABC nerve can be elevated with the flap or left in situ. The ulnar artery and nerve must be protected.
- The main perforator is skeletonized as necessary to permit adequate rotation of the flap and to prevent pedicle kinking.¹²
- Additional perforators are clamped, and flap vascularity is assessed.
 - If perfusion is maintained, the additional perforators are divided.
 - If not, the additional perforators are maintained to ensure flap viability.
- The flap is inset into the defect. It can be rotated up to 180 degrees (**TECH FIG 1B,C**).
- If used as a sensory flap, the MABC is coapted to a sensory nerve located within or adjacent to the defect.
- The flap donor site is closed primarily for flaps up to 6 cm in width (**TECH FIG 1D**) or using a STSG if a wider flap is harvested.
- A drain can be placed under the flap or the donor site.
- Antibiotic-impregnated gauze is placed over all incisions and covered with sterile gauze. The flap is left uncovered to facilitate postoperative flap monitoring.
- A well-padded splint is applied to protect the flap and to decrease tension on the flap.
 - When the flap is used for coverage of palmar defects, the wrist is splinted in mild flexion to decrease flap tension.
 - When used for dorsal defects, the wrist is splinted in extension.

TECH FIG 1 • **A.** Following debridement of a traumatic wound, this patient had a 9 × 4 cm defect over the dorsal ulnar hand with exposed extensor tendons. An ulnar artery perforator flap was designed as a propeller flap for coverage. The width of the flap is designed to match the width of the defect. The length of the flap is marked so that when the flap is rotated 180 degrees around the perforator, the proximal edge of the flap will reach the distal edge of the defect. An umbilical tape, vessel loop, or surgical sponge can be used to visualize the arc of rotation of the proximal flap into the distal defect during flap marking. **B.** The ulnar artery perforator flap is elevated. **C.** The flap can be rotated up to 180 degrees into the distal defect. **D.** Here, the donor site was closed primarily. The flap width was 4 cm. Flaps widths up to 6 cm can generally be closed with sutures directly. Wider flaps require closure with an STSG.

PEARLS AND PITFALLS

Physical findings

- A modified Allen test is performed to assess the patency of the palmar arch. An intact palmar arch is not required for the ulnar artery perforator flap but provides valuable information about the arterial supply of the hand.

Technique

- During ulnar artery perforator flap elevation, the dorsal sensory branch of the ulnar nerve may require division. In these cases, the

	nerve should be repaired using 9-0 nylon suture or fibrin glue. ■ Dissection of the dorsal branch of the ulnar artery to its origin from the ulnar artery facilitates rotation of the flap up to 180 degrees.⁸
Postoperative	■ The patient is instructed to keep the hand elevated following flap coverage. This decreases flap edema, which lessens the risk of pedicle compression and venous congestion.
Therapy	■ The fingers, wrist, and forearm can be passively mobilized in the operating room to assess for flap tension with movement. Immediate range of motion exercises are performed for uninvolved joints that do not cause strain on the repair with motion.

POSTOPERATIVE CARE

- The patient is monitored in hospital for signs of flap compromise.
 - Poor arterial inflow or venous congestion should prompt removal of the dressings, flap assessment, and urgent return to the operating room to assess for pedicle compromise due to hematoma, kinking, or compression.
- The patient is discharged on postoperative day 3.
- The patient returns to clinic 1 week postoperatively for a dressing change.
- A thermoplastic splint can be worn for an additional week if range of motion causes tension on the flap.
- Range of motion exercises are started under the guidance of a hand therapist 1 week postoperatively and advanced weekly.

OUTCOMES

- The ulnar artery perforator flap provides thin, durable soft issue coverage in a single-stage operation (**FIG 6**).
- Compared to the radial forearm flap, the ulnar artery perforator flap donor site is less visible on the forearm and the skin paddle contains less hair.
- The ulnar artery perforator flap provides an excellent color match for dorsal wrist and hand defects.
 - In dark-skinned patients, the color is not as well matched for palmar defects.

FIG 6 • The ulnar artery perforator flap at 1 **(A)** and 10 **(B)** months postoperatively. Supple, durable, thin soft tissue coverage is provided for defects of the hand. The donor site heals well with minimal morbidity.

COMPLICATIONS

- The MABC can be harvested with the flap to restore sensation at the defect site. The donor-site sensory deficit is minimal because of existing sensory overlap and subsequent sensory axon in-growth from neighboring nerves to the denervated skin.¹³
- The risk of venous congestion is lower for the ulnar artery perforator flap compared to reverse flow flaps, such as the reverse radial forearm flap or the reverse posterior interosseous flap. The ulnar artery perforator flap is a distally based island flap, not a reverse flow flap.
- Incisions over the ulnar forearm, wrist, and hand can be sensitive. Scar massage is recommended once the incisions are healed, starting approximately 3 weeks postoperatively.

49 Posterior Interosseous Artery Flap

CHAPTER

Kate Elzinga and Kevin C. Chung

DEFINITION

- The posterior interosseous artery (PIA) flap is a perforator flap used for coverage of upper extremity defects. Its harvest avoids the sacrifice of a major artery, such as that of the radial artery during harvest of the radial artery flap.
 - It is available in patients without an intact palmar arterial arch.
- The PIA flap is typically used as a pedicled flap. It can also be harvested as a free flap.¹
- The PIA flap is most commonly used as a retrograde regional flap based on the anteroposterior interosseous artery system to cover defects of the first web space, dorsal wrist, dorsal and volar hand, and dorsal thumb up to the proximal interphalangeal joint.
 - The PIA flap can also be used as an antegrade flap for defects of the elbow, antecubital fossa, and proximal volar forearm.
- The dimensions of the PIA flap are designed based on the defect size.
 - One case series of 53 patients, from whom two-thirds of the circumference of the forearm skin was harvested, reported the use of PIA flaps from 5×2.5 cm to 21×10 cm in size.²
- The PIA flap provides a good color match for defects of the forearm, wrist, and hand, particularly dorsally.
 - In dark-skinned patients, resurfacing of the palmar skin with a PIA flap leads to a color mismatch.

ANATOMY

- The PIA flap is classified as a Mathes and Nahai type B flap; it is supplied by a septocutaneous perforator.

- Most commonly, the flap is harvested subfascially as a fasciocutaneous island flap.
- It can also be harvested with a skin bridge or as an adipofascial flap, which permits primary closure of the donor site; the subcutaneous tissue and fascia are harvested; the dermis is preserved at the donor site.³
- When used as an adipofascial flap, the flap is covered with a split-thickness skin graft (STSG) after inset.
- The flap pedicle is composed of the PIA and its two adjacent vena comitantes.
 - Proximally, the artery is 1.2 to 2.1 mm in diameter and the vena comitantes are 1.0 mm.
 - Over the middle third of the forearm, the PIA has its narrowest caliber, measuring 0.5 mm.
 - Distally, it measures 0.9 to 1.1 mm.⁴
- The PIA arises 4 cm from the lateral epicondyle from the common interosseous artery in 80% of cases and directly from the ulnar artery in 20% of cases.⁵
- The anterior interosseous artery (AIA) also arises from the common interosseous artery, or less commonly, directly from the ulnar artery. It runs along the volar surface of the interosseous membrane (IOM), deep to the flexor digitorum profundus and flexor pollicis longus.
- The PIA passes through the IOM from the volar forearm to the dorsal forearm 8 cm distal to the lateral epicondyle and 14.5 cm proximal to the ulnar styloid.⁵
 - In most cases, it gives origin to three fasciocutaneous perforators to the overlying skin in the proximal forearm and six to eight perforators in the distal forearm.⁴
 - The PIA runs with the posterior interosseous nerve (PIN) along the dorsal IOM to the hand in the septum between the extensor digiti minimi (EDM) and extensor carpi ulnaris (ECU).
- After passing under the supinator in the proximal forearm, the PIA runs over the abductor pollicis longus, extensor pollicis longus, extensor pollicis brevis, and extensor indicis proprius (**FIG 1**).
- Two centimeters proximal to the distal radioulnar joint (DRUJ), just proximal and radial to the head of the ulna, a branch of the PIA travels volarly through the IOM and anastomoses with the dorsal branch of the AIA.
 - This anastomotic connection is the basis for the retrograde PIA flap.
- The PIA continues distally and joins the dorsal carpal arch. The retrograde PIA

flap also receives some flow through this arch.

- The axis of the flap is marked from the lateral epicondyle of the elbow to the head of the ulna.⁵
- The flap design is centered on the septum between the EDM and ECU to maximize the number of perforators entering the flap from the PIA between the dorsal margins of the ulna and radius (**FIG 2**).
- The flap is typically designed up to 18 × 8 cm in size.
- A segment of the proximal third of the ulna, with a cuff of the extensor pollicis longus, can be included in the PIA flap for use as an osteocutaneous flap.⁶

PATIENT HISTORY AND PHYSICAL FINDINGS

- Important aspects of the patient history include age, sex, handedness, occupation and avocations, past medical history, medications, allergies, smoking and recreational drug use, and previous injury to the affected arm.
- The wound is evaluated for
 - Exposed and damaged structures—skin, tendons, neurovascular structures, bone
 - Health of remaining structures—tissue necrosis, contamination, signs of infection
 - Local and regional donor sites

FIG 1 • The course of the posterior interosseous artery is shown in the dorsal forearm. It originates from the

common interosseous artery, or less commonly, from the ulnar artery directly. It passes under the supinator and then travels over the abductor pollicis longus, extensor pollicis longus, extensor pollicis brevis, and extensor indicis proprius. Two centimeter proximal to the DRUJ, a branch of the PIA travels volarly through the IOM to form an anastomosis with the dorsal branch of the AIA. The PIA continues distally to contribute to the dorsal carpal arch. The axis of the flap is marked from the lateral epicondyle to the head of the ulna to maximize the capture of PIA perforators into the flap.

- Radiographic imaging is used in conjunction with physical examination to determine the presence and extent of bone injuries.
- Skin and soft tissue defects can be adequately reconstructed using soft tissue flaps.
 - When the defect size is too large for local flap coverage, the PIA flap is a useful regional flap that can be performed. It alleviates the need for a microsurgical free flap from a distant donor site.
- Many tendon and bony defects can be reconstructed in the hand and then covered with a PIA flap during the same operation. This fasciocutaneous flap provides reliable, durable soft tissue coverage of exposed structures and a smooth gliding surface for underlying tendons.
- Skin laxity is assessed over the dorsal forearm using a pinch test.
 - Flaps larger than 4 to 6 cm in width typically require donor site closure with a skin graft.
 - If desired, the skin graft can be excised later using serial excision; the patient must be appropriately counseled prior to flap reconstruction regarding the expected appearance of the donor site given its visible location over the dorsal forearm.

IMAGING

- Radiographs are performed of the injured extremity to assess for fractures or foreign bodies.
- Angiography is not routinely performed prior to PIA flap reconstruction.

- If there is concern of the integrity of the PIA or AIA-PIA anastomotic arch, angiography can be considered to evaluate the vessels or a different flap can be selected.

FIG 2 • The PIA perforators run in the interval between the EDM and ECU to supply the overlying skin. The AIA runs volar to the IOM in the forearm. Distally, 2 cm proximal to the DRUJ, the AIA gives off a dorsal branch that forms an anastomosis with the PIA.

NONOPERATIVE MANAGEMENT

- The wound must be adequately debrided and cleansed prior to flap reconstruction. Following traumatic injury, the wound is explored, injured structures are assessed, and necrotic tissue is debrided. Once the wound is clean and the tissues have demarcated, flap reconstruction can proceed.
- For the reconstruction of oncologic defects, final tumor pathology and negative margins are established prior to flap closure.
- Moist, antibacterial dressings can be used in the interim to minimize tissue desiccation and bacterial load.

SURGICAL MANAGEMENT

- Local flaps are limited to coverage of small defects of the upper extremity.
- Larger regional flaps, such as the PIA flap, provide coverage of forearm, wrist,

and hand defects without the need for free flap microsurgical reconstruction (**FIG 3**).

- Compared with free flaps, pedicled flaps require less general anesthesia time, avoid the need for flap harvest from an uninjured limb or the trunk, and are options when microsurgical equipment or expertise is unavailable.

FIG 3 • This patient underwent a ray resection of the thumb for treatment of squamous cell carcinoma. In-transit metastases were resected from the volar radial forearm. Following pathological confirmation of negative margins at both locations, a PIA flap was used for coverage of the exposed trapezium at the base of the radial hand wound. (Courtesy of Steven Haase, MD.)

Preoperative Planning

- The risks and benefits of flap reconstruction with a PIA flap are reviewed with the patient.
 - The benefits include provision of durable, supple soft tissue coverage, a donor site limited to the affected upper extremity, and a single-stage procedure.
 - The risks include partial or complete flap failure and injury to the PIN. The patient is counseled that the PIA flap has a visible donor site.
- When used as a retrograde flap, the PIA flap is insensate.
 - For antegrade or free PIA flaps, the posterior antebrachial cutaneous nerve of the forearm can be included for sensory restoration.
- Previous injury to the PIA flap donor site is a contraindication to its use.
 - The PIA perforators are small and thin-walled, so crush or shear injury to dorsal forearm makes flap harvest unreliable.
- Injury to the DRUJ and possible damage to the AIA-PIA anastomosis

precludes retrograde PIA flap use.

- Some authors have reported the absence of the AIA-PIA anastomosis or a hypoplastic or absent PIA in the middle third of the forearm. Penteado reported 5 such cases in 110 cadavers, Angrigiani reported 1 case in 80 patients, and Buchler reported 2 cases in 36 patients.⁷⁻⁹
- Anatomic dissections have confirmed the reliability of the AIA-PIA system and presence of the PIA throughout the dorsal forearm.^{5,7} Studies have noted that the PIA is more superficial and narrowest in caliber over the dorsal third of the forearm, measuring 0.5 mm.
- If there are doubts of the integrity of the PIA, the incision can be closed and another flap can be used.
- In rare cases, if the PIA is absent or hypoplastic, the AIA is dominant and an AIA perforator flap can be harvested instead.^{10,11}

Positioning

- The patient is positioned supine with the arm out on a hand table.
- A tourniquet is placed on the upper arm of the affected limb.
- If the PIA flap is harvested with a width over 4 to 6 cm, closure with a skin graft is typically required. Most commonly, the patient's ipsilateral thigh is used for STSG harvest.

Approach

- Loupes are worn for flap harvest and inset. An operating microscope is not routinely required; in rare cases, it may be employed if there is difficulty visualizing the vascular anatomy or concern of pedicle injury during flap harvest.
- The flap incisions are designed, most commonly as a longitudinal ellipse.
- The arm is then elevated and the tourniquet is inflated.
- Exsanguination with an Esmarch bandage is avoided to maintain visibility of the PIA and its perforators.

TECHNIQUES

- The axis of the flap is marked with the forearm in full pronation from the lateral epicondyle to the ulnar head. This marks the course of the PIA.
- A Doppler ultrasound is used to identify perforators running along this axis

to the overlying skin. Typically, there is a large perforator found at the midpoint of the dorsal forearm, along the flap axis. The skin flap is designed to include this perforator and as many additional perforators as possible.

- To raise a fascia-only flap, the dorsal forearm fascia is exposed by incising the skin above the flap and elevating thin dermal flaps bilaterally.
- To raise a fasciocutaneous flap, the skin, subcutaneous tissue, and fascia are raised en bloc. Once elevated, it is recommended that the dermis is sutured to the underlying fascia using absorbable sutures to prevent shearing of the perforators to the skin.

■ Retrograde PIA Flap

- The pivot point of the flap is marked 2 cm proximal to the DRUJ, proximal to the edge of the extensor retinaculum, at the site of the AIA-PIA anastomosis (**TECH FIG 1A**).
- The rotation of the flap into the defect is tested using a sponge, umbilical tape, or vessel loop.
- The flap is typically designed at the junction of the proximal and middle thirds or over the middle third of the dorsal forearm to include the skin perforators arising distal to the supinator while permitting tension-free rotation into the distal defect of the wrist, hand, or first web space (**TECH FIG 1B**).
- The proximal flap limit is marked 3 cm distal to the lateral epicondyle. Proximally, there are no PIA perforators to the overlying skin.¹²

TECH FIG 1 • A. The axis of the PIA flap runs from the lateral epicondyle to the head of the ulna. The retrograde PIA flap is centered over the junction of the proximal and middle thirds of the forearm or over the middle third of the forearm based on the arc of rotation required to reach the defect. The flap pivot point is marked 2 cm proximal to the DRUJ. A large perforator is typically found near the midpoint of the dorsal forearm from the PIA to the overlying skin. The proximal flap limit is marked 3 cm distal to the lateral epicondyle. **B.** The flap axis is marked from the lateral epicondyle to the ulnar head with the forearm in full pronation. The pivot point is marked 2 cm proximal to the DRUJ. A Doppler ultrasound is used to mark skin perforators. The flap is designed as an ellipse over the proximal and middle thirds of the forearm to include audible skin perforators. The flap can be elevated as an island flap or with a skin bridge as shown here. The skin bridge overlies the pedicle and is elevated by incising a 1-cm strip of dermis (marked here in *solid lines*). An additional 0.75 cm of subcutaneous fat and fascia is included on either side of the dermis to protect the PIA and its vena comitantes (marked here with *dotted lines*). An incision is marked from the flap pivot point to the defect for inset of the flap (marked here with a *solid line* from the pivot point in a radial oblique direction to the thumb defect).

- A template of the defect is made using Telfa and used to mark the appropriate flap dimensions, up to 18 × 8 cm in size.
- The interval between the fifth and sixth extensor compartments can be palpated; the PIA is found in the septum between the EDM and ECU.
- The flap is centered over this interval.

- The flap can be elevated as an island flap, or with a 1-cm skin bridge that can be closed primarily.
 - The skin bridge protects the pedicle, prevents kinking of the vessels on inset, and makes flap harvest safer.

Retrograde PIA Island Flap Harvest

- To raise the flap as an island flap, dissection is typically started distally by incising through the skin and subcutaneous tissue and identifying the PIA in the septum between the fifth and sixth extensor compartments (**TECH FIG 2A**).
 - The pedicle can be followed proximally to the distal edge of the flap. The flap markings are adjusted if needed to ensure that the flap is centered over the pedicle.
 - This is a most reliable way to ensure that the flap has been properly designed prior to elevation.
- The flap is raised subfascially from its ulnar border to the intermuscular septum (IMS) between the EDM and ECU (**TECH FIG 2B**).
- Next, elevation proceeds from the radial border of the flap, again toward the IMS between the EDM and ECU.
- Distal to the supinator, the PIN gives a branch to the ECU that crosses superficial to the PIA (**TECH FIG 2C**). The PIA is divided just distal to this nerve branch.
- Flap elevation proceeds from proximal to distal. The PIN runs with the PIA along the dorsal forearm and is protected throughout flap elevation.
- The pedicle is raised as a fascial strip between EDM and ECU containing the PIA and its vena comitantes.
- The PIA gives off multiple branches to the surrounding musculature; these are divided using microclips and bipolar cautery.

Retrograde PIA Flap Harvest With a Skin Bridge

- To raise a flap with a skin bridge, the flap is elevated first from its ulnar border in a subfascial plane toward the IMS between the EDM and ECU.
 - Gentle proximal traction on the muscle bellies confirms the anatomy; traction on the EDM will extend the small finger while traction on the ECU will extend the wrist.

TECH FIG 2 • A. To confirm the flap is properly centered over the PIA, dissection starts distally. The PIA is identified in the interval between the EDM and ECU over the dorsal wrist. The flap design is confirmed over the proximal-middle forearm to ensure the PIA will be centered within it and then the flap is elevated. **B.** The PIA flap is raised subfascially, here shown from ulnar to radial. Perforators can be seen entering the flap in the interval between the EDM and ECU from the PIA below. **C.** The PIN gives a motor branch to the ECU distal to the supinator (shown here on top of the blue background material). This branch crosses superficial to the PIA. It is protected. The PIA and its vena comitantes are divided just distal to this nerve branch and then the flap is elevated from proximal to distal for retrograde use.

■ Next, the radial border of the flap is raised toward the IMS between the

EDM and ECU. The IMS between the extensor digitorum communis (EDC) and EDM will be encountered. The EDM is much smaller in size compared to the EDC that is found one interval radially. To elevate the flap subfascially above the EDC, the flap fascia is divided from the IMS between the EDC and EDM.

- Proximal retraction of the EDM radially and the ECU ulnarly with a self-retaining retractor facilitates exposure of the PIA (**TECH FIG 3A,B**).
- The skin bridge is incised from proximal to distal, a few centimeters at a time.
 - The pedicle location is confirmed sequentially.
 - The course of the skin bridge can be modified if needed to ensure the pedicle is maintained within it.
 - A 1-cm dermal bridge is used. An additional 0.75 cm cuff of subcutaneous fat and fascia is harvested on each side of the skin bridge to protect the pedicle.
 - Restricting the width of the dermis elevation to 1 cm facilitates primary closure of this area.
- Distally, the pedicle is closely associated with the periosteum of the ulna. Ulnar retraction of the ECU tendon exposes the PIA (**TECH FIG 3C**).

Retrograde PIA Flap Inset

- Once flap elevation has reached the pivot point, 2 cm proximal to the DRUJ, dissection stops.
- The tourniquet is deflated and flap color, capillary refill, temperature, and turgor are assessed.
 - Arterial bleeding is noted from the flap edges.

TECH FIG 3 • A. Radial retraction of the EDM and ulnar retraction of the ECU proximally facilitates exposure of the PIA and PIN in the septum between these muscles. **B.** The PIA and its vena comitantes are shown running centrally on the undersurface of the flap. The PIN is protected and left in situ between

the EDM and ECU. Branches of the PIA to the surrounding musculature are divided as the flap is elevated. **C.** The PIA is closely associated with the periosteum of the ulna distally. The ECU tendon is retracted ulnarly to facilitate elevation of the flap pedicle.

TECH FIG 4 • A. An incision is made from the flap pivot point to the thumb defect to permit inset of the flap. Dorsal veins and branches of the radial sensory nerve are protected. Alternatively, a wide subcutaneous tunnel could have been used to pass the flap into the defect. The flap is shown with its pedicle centered on the undersurface. The donor-site extensor musculature offers a well-vascularized wound bed for reliable STSG graft take. The skin bridge defect is shown here tacked closed with towel clips; primarily closure will be performed. **B.** The flap is inset without tension into the defect. Release of the dermis over the skin bridge at the flap pivot point facilitates flap rotation and skin inset. The donor site is closed with an STSG from the ipsilateral thigh. A small drain can be placed under the flap, away from the pedicle.

- The AIA-PIA anastomotic connection is reliable and does not need to be skeletonized to confirm its presence unless there are concerns with flap perfusion.
- The flap is rotated into the defect. It can be tunneled into the wound.

- To minimize the risk of pedicle compression and vascular compromise, we typically prefer to make an incision between the flap pivot point and the defect for inset (**TECH FIG 4A**). Skin flaps are elevated along this incision to achieve sufficient mobility to permit tension-free closure over the pedicle.
- Alternatively, the pedicle can be covered with a skin graft.
- For volar palm defects, the flap can be passed around the ulnar border of the hand or through the IOM using a wide tunnel.¹³
- The flap is inset into the defect and secured with sutures; it can be rotated up to 180 degrees.
 - The pedicle is carefully rotated at the pivot point to avoid kinking.
 - If a skin bridge has been used, release of the dermis at the pivot point can facilitate inset.
 - A small-caliber drain can be placed under the flap, away from the pedicle, if desired (**TECH FIG 4B**).
- Narrow flap donor sites are closed primarily.
 - For flap donors site over 4 to 6 cm in width, a split-thickness skin graft (STSG) is used for closure.
- Antibiotic-impregnated gauze is applied to the flap incisions and covered with sterile gauze.
 - The flap skin paddle is left exposed for monitoring in the postoperative period.
- Antibiotic-impregnated gauze is placed over the STSG at the flap donor site and covered with sterile gauze and an elastic bandage to apply gentle compression and to avoid shear of the STSG.
- The wrist and hand are immobilized with a well-padded splint.

■ Antegrade PIA Flap

- The axis of the flap is marked from the lateral epicondyle to the head of the ulna. The flap is designed at the junction of the middle and distal thirds of the dorsal forearm.
 - The distal edge of the flap is marked 4 cm proximal to the wrist to avoid injury to the dorsal sensory branch of the ulnar nerve.
- The radial aspect of the flap is incised.
- The flap is raised from radial to ulnar in the subfascial plane toward the IMS

between the EDM and ECU.

- The PIA and its perforators are visualized.
- The flap design is confirmed, ensuring the perforators enter the center of the flap, and then the ulnar incision is made.
 - The flap is raised to the IMS between the EDM and ECU in an ulnar to radial direction.
- Distal to the flap, the anastomotic branch of the PIA to the AIA is identified and ligated.
- The flap is elevated from distal to proximal, following the pedicle in the septum between the EDM and ECU.
 - The flap is typically raised as an island flap.
 - The dorsal sensory branch of the ulnar nerve and the PIN are protected at all times.
- The flap is inset into the defect; it can be rotated up to 180 degrees.
 - Care is taken to avoid pedicle kinking and compression as the flap is sutured.
- The flap donor site is closed primarily or with an STSG.
- The incisions are covered with antibiotic-impregnated gauze and dry sterile gauze.
 - The visibility of the flap skin paddle is necessary for flap monitoring.
- If used, the STSG is dressed with antibiotic-impregnated gauze and covered with sterile gauze and an elastic bandage.
- The elbow is immobilized with a well-padded splint, avoiding pressure on the flap and pedicle.

PEARLS AND PITFALLS

Physical findings

- The PIN must be protected throughout flap elevation. The PIA pedicle is dissected away from the PIN. If branches of the PIN cross superficial to the PIA and impede flap elevation, the flap can be converted to a free flap.
- The PIA flap offers a better skin color match than the radial forearm flap for defects of the dorsal hand and first web space.

Technique

- The vena comitantes of the PIA are small. To optimize the chances

	of flap survival, a cutaneous vein is raised with the flap to permit venous supercharging if venous congestion is noted after flap inset. ■ When harvesting a retrograde PIA flap, it is wise to harvest the PIA and its vena comitantes at least 1 cm proximal to the proximal flap edge. This also permits supercharging of the flap if there is poor arterial inflow through the PIA-AIA anastomosis or venous congestion. Conversion to a free flap is also possible. ■ Often the proximal and distal margins of the flap can be closed primarily. If the central flap width is over 4–6 cm, depending on the skin laxity, a skin graft may be required for closure. A sheet STSG is preferred rather than a meshed STSG for improved donor-site appearance.⁴ ■ For large defects, the PIA flap can be harvested simultaneously with an ipsilateral lateral arm flap.¹⁴ The two skin paddles are elevated together.
Postoperative care	■ Partial or complete flap necrosis is uncommon.^{5,12} However, the patient must be counseled preoperatively of the risk of flap necrosis and the need for a second flap.
Therapy	■ After flap inset, the elbow, wrist, and fingers are moved passively to evaluate the effect of joint range of motion on the flap. Tension-free inset is ideal; this permits early range of motion exercises starting 5 days postoperatively after the donor site graft has taken.

POSTOPERATIVE CARE

- Flap checks are performed every 2 hours for the first 24 hours postoperatively and then every 4 hours.
 - Tissue turgor, color, capillary refill, and temperature are monitored.
 - Any change in flap status, indicating possible arterial or venous insufficiency, should prompt a return to the operating room for flap assessment.
 - Compression by a hematoma or pedicle kinking is a common cause of flap insufficiency.
- The patient is typically discharged home on postoperative day 3.
- The patient returns to clinic on postoperative day 5 to assess the skin graft take and replace the dressings.
 - The splint is discontinued following this dressing change after confirming that the flap does not experience undue tension with elbow, wrist, and hand range of motion.
 - If there are concerns, the splint can be continued for an additional week.

OUTCOMES

- The PIA flap provides reliable soft tissue coverage for upper extremity defects.
- Along with the radial forearm flap, it is a valuable option for pedicled flap coverage of the wrist and hand.

COMPLICATIONS

- Most of the lymphatic drainage from the hand runs over the volar forearm. Compared with the radial forearm free flap, the PIA flap disrupts less lymphatic outflow that results in less edema postoperatively.
- PIN palsy is rare following PIA flap harvest. Motor functions of the muscles of the extensor compartment of the forearm are tested postoperatively to confirm PIN innervation.

51 Pedicled and Free Groin Flap

CHAPTER

Mark Morris and Kevin C. Chung

DEFINITION

- A free flap requires the transfer of tissue from one body site to another, with anastomosis of arterial and venous systems to the recipient site using microsurgical techniques.
- A pedicled flap transposes tissue from a donor site to a recipient site while keeping the tissue partially attached to the donor site. The donor vascular pedicle is left intact to supply the flap. Pedicled flaps are reliable and do not require microsurgery.
- The groin flap was described in 1972 by McGregor and Jackson¹ for reconstruction of soft tissue defects of the hand. This was once a “workhorse” flap for hand reconstruction; however, with the introduction and advancement of microsurgery, it has fallen out of favor for many indications. Nevertheless, there are still many indications for its use.
- When a pedicled groin flap is used, patients must be counseled that they will require multiple operations (average 4.6 operations per patient), including flap division, debulking, and tissue rearrangement for contouring.²

ANATOMY

- The groin flap is based on the superficial circumflex iliac artery (SCIA).
 - The SCIA arises approximately 2 to 3 cm distal to the inguinal ligament, either directly from the femoral artery (70%) or from the superficial inferior epigastric artery (**FIG 1**).
 - The SCIA passes laterally from its origin and gives a deep branch at the medial border of the sartorius.
 - The superficial branch then pierces the fascia at the lateral border of the

sartorius and runs 2 to 3 cm distal and parallel to the inguinal ligament, toward the anterior superior iliac spine (ASIS). This superficial branch supplies the skin to be used for the flap.

- After reaching the ASIS, the superficial branch of the SCIA branches further and anastomoses with branches of the superior gluteal, deep circumflex iliac, and ascending lateral femoral circumflex arteries.
- The SCIA pedicle is generally between 0.8 and 1.8 mm in diameter.³

FIG 1 • Vascular and regional anatomy of the groin flap, which follows the axis of the superficial circumflex iliac artery.

FIG 2 • Limits of the groin flap.

- Venous drainage of the flap is split between the superficial circumflex iliac vein and the venae comitantes of the SCIA. Both of these eventually drain into the femoral vein, either directly or via the saphenous vein.
- Flap size is limited to about 13×10 cm (**FIG 2**). The axis of the SCIA is marked by palpating the femoral pulse, marking the origin 2 to 3 cm distal to the inguinal ligament and then drawing a line to the ASIS. The flap will follow this axis.
- The medial boundary of the flap is about 3 to 4 cm lateral to the femoral artery (2–3 cm medial to the medial border of the sartorius).
- The maximum width of the flap that can be primarily closed in most patients is 10 cm. The flap should be positioned two-thirds superior to the vascular axis and one-third below the axis. This translates to up to 6 to 7 cm superior to

the axis and 3 to 4 cm inferior to the axis.

- The lateral portion of the flap should be designed with a 1:1 length-to-width ratio. This is because the portion of the flap lateral to the ASIS has a random pattern of vascularization. Therefore, because the width of the flap is limited to 10 cm, the lateral limit of the flap is then 10 cm lateral to the ASIS.
- Sensation to the lateral portion of the groin flap is supplied by the lateral cutaneous branches of the 12th thoracic subcostal nerve (**FIG 3**).⁴ This nerve can be harvested with the flap to provide sensation to the hand, but a sensate nerve is infrequently used.
- The 12th thoracic nerve pierces the internal and external oblique muscles and courses distally over the iliac crest, 5 cm posterior to the ASIS. Do not confuse the lateral femoral cutaneous nerve, which supplies sensation to the lateral thigh, for the 12th thoracic nerve.

Lateral cutaneous
branch of 12th
thoracic nerve

FIG 3 • The lateral cutaneous branch of the 12th thoracic nerve enters the graft opposite the vascular pedicle.

PATIENT HISTORY AND PHYSICAL FINDINGS

- History must include the mechanism of injury.
 - Crush and blast injuries can lead to a much larger zone of injury than expected by initial examination (**FIG 4A,B**).
 - In the case of a crush injury, the physician must also assess the patient for signs of compartment syndrome.
- Contaminated wounds may require multiple irrigation and debridement procedures (**FIG 4C–E**).
- Medical and social history—such as diabetes mellitus, peripheral vascular disease, or smoking—does not contraindicate surgery but will affect the healing potential of the flap and must be discussed with the patient.
- Assess the vascular status of the remaining limb.
- Motor and sensory evaluation to assess damage to nerves, tendons, or muscles.

IMAGING

- Standard radiographs of the hand are done to evaluate for bony injury.

SURGICAL MANAGEMENT

- Free flaps are generally considered superior to the pedicled groin flap with today's microsurgical techniques. However, there are still many good indications for doing a pedicled groin flap:
 - Complex hand injuries in young children (less than 2 years). Microsurgery in infants is technically challenging because of the small size of the vessels.
 - In preparation for a toe-to-thumb transfer following thumb or finger loss. This preserves the recipient vessels for later microsurgery during transfer and also saves as much stump tissue as possible by providing coverage.

FIG 4 • A,B. Preoperative radiograph and clinical photograph, respectively, of a 12-year-old boy who sustained a bomb-blast injury to the left upper extremity. **C–E.** Images after left hand radical debridement, open reduction and internal fixation of the left thumb metacarpal using K-wires, and left index finger metacarpal transposition to the small finger and fixation with K-wires.

- Dorsal or palmar soft tissue defects involving multiple digits
- Degloving injury to all fingers
- Circumferential thumb soft tissue defect
- First stage of an osteoplastic thumb reconstruction
- High-voltage electrical burns with a hand surviving on collateral circulation. In some cases, a hand may survive based on collateral blood supply when both ulnar and radial arteries have thrombosed in the forearm. The extensive zone of injury affects available recipient vessels, and dissection of these vessels may inadvertently lead to hand necrosis.⁵
- Advantages to the pedicled groin flap are that it is thin and nearly hairless, it is reliable, flap elevation is quick, and the donor site can be closed primarily in

most cases.

- Disadvantages of the pedicled groin flap are that it is a mandatory two-stage operation, the patient's hand is connected to his or her groin for 3 to 4 weeks (which leads to stiffness in the shoulder, elbow, and wrist, especially in older patients), and there is a high risk of injury to the lateral femoral cutaneous nerve with subsequent loss of sensation in the lateral thigh or a painful neuroma.

Preoperative Planning

- The following is a rough guideline for skin requirements for reconstruction in an adult male:
 - Thumb (circumferential)
 - Distal to the metacarpophalangeal joint: 9×8 cm
 - Distal to the thenar crease: 13×12 cm
 - Palmar hand: 12×10 cm
 - Dorsal hand: 12×10 cm
 - Finger (circumferential): 7×10 cm
- Assess for any scars in the groin.
- Use a Doppler probe to confirm the location of the SCIA.

Positioning

- The patient is positioned supine on the operating table with a hand table in place.
- A bump is placed under the ipsilateral hip to better visualize the elevation of the random portion of the flap lateral to the ASIS.
- The operative extremity and ipsilateral groin are prepped and draped widely.
- A tourniquet is placed on the upper extremity.

Approach

- The wound must be thoroughly debrided back to healthy tissue.
- Keep in mind the above-mentioned limits of the flap when designing the groin flap.
- Bone fixation and nerve reconstruction can be performed at the same time as the groin flap; however, tendon reconstruction should be delayed until passive joint range of motion is re-established for rehabilitation purposes.
- The surgeon must decide on whether or not to attempt an innervated flap prior

to elevating the flap, as the lateral cutaneous branch of the 12th thoracic nerve will have to be harvested if this is desired.

TECHNIQUES

■ Pedicled Groin Flap

Flap Design

- Mark the inguinal ligament from the pubic tubercle to the anterior superior iliac spine (ASIS).
- Palpate the femoral pulse.
 - Mark the origin of the superficial circumflex iliac artery (SCIA) off of the femoral artery, 2 to 3 cm distal to the inguinal ligament (**TECH FIG 1**).
 - Draw another line perpendicular to the first line, 2 to 3 cm inferior to the inguinal ligament. This marks the axis of the SCIA. This can be confirmed with a Doppler probe.
- Make a template of the defect and transfer it to the groin within the limits of the graft discussed earlier.

Flap Harvest

- Elevate the flap starting at the superolateral margin.
 - The incision is taken down to the level of the external oblique aponeurosis. The flap is elevated in this plane from lateral to medial (**TECH FIG 2A**).
 - If an innervated flap is desired, the surgeon must identify the lateral cutaneous branch of the 12th thoracic nerve. This nerve pierces the internal and external oblique muscles and descends 5 cm posterior to the ASIS. Harvest the nerve at this time as it enters the lateral portion of the flap.
- Elevate the lateral and inferior margins of the flap.
 - The inferior portion of the flap is elevated superficial to the fascia lata.
- The random portion of the flap is elevated to the ASIS.
 - The lateral borders of the sartorius and fascia lata are identified inferior to the ASIS.

TECH FIG 1• Markings for a pedicled groin flap.

- Elevate the axial portion of the flap.
 - An incision is made longitudinally over the fascia lata and sartorius fascia. The flap is now elevated in this deeper plane to include this layer of sartorial fascia medial to the ASIS (**TECH FIG 2B**). This is critical because the SCIA is superficial to the fascia over the sartorius. Elevating the sartorial fascia protects the SCIA. This also prevents the fascia from tethering and kinking the vessel, which could cause flap necrosis. The SCIA does not need to be isolated for the pedicled flap.
 - Identify and ligate the deep branch of the SCIA. It will arise at the medial border of the sartorius. The deep branch is very short and should be ligated within the substance of the sartorius to avoid injury to the SCIA.
 - Identify and protect the lateral femoral cutaneous nerve as it arises beneath the inguinal ligament, near the medial border of the sartorius.
 - Divide any connections between the inguinal ligament and fascia lata.
 - The flap can be elevated 2 to 3 cm medial to the medial border of the sartorius.
- Close the flap donor site.
 - Close from medial to lateral in layers.
 - A drain is not usually required if adequate hemostasis was attained. The

closure is tight and should compress the bed sufficiently, so fluid collection under the flap is not a concern.

- Undermining skin flaps and hip flexion will assist with closure. The bump can also be removed from under the hip.

Flap Placement and Division

- Thin the flap to match the thickness of the recipient site.
 - The random portion of the flap lateral to the ASIS can be made thin safely because the flap relies on the subdermal plexus in this location.
 - Leaving excess fat increases vascular demands of the flap.
- The 12th thoracic nerve can now be repaired to an available digital nerve from the recipient hand if an innervated flap is planned.
- Inset the flap to the recipient site using 3-0 nylon interrupted sutures (**TECH FIG 3A,B**).
- Flap division generally occurs after 3 weeks (**TECH FIG 3C–F**).
- The surgeon can passively move the patient's shoulder, elbow, and hand while still under anesthesia after division.
 - This will break up adhesions and facilitate recovery of motion postoperatively.

TECH FIG 2• A. The flap is elevated from lateral to medial, superficial to the external oblique aponeurosis. **B.** The sartorius fascia is raised with the SCIA pedicle

as the flap is elevated from lateral to medial.

TECH FIG 3 • **A,B.** Images after the groin flap has been inset to the left hand. **C–F.** Postoperative images after flap division.

■ Free Groin Flap

Flap Design

- Follow the same steps as for a pedicled flap to plan and elevate the free flap, except that the medial portion of the flap must also be elevated.
- The free flap can be harvested from the contralateral or ipsilateral groin.
- Free groin flap is seldom performed because of the short pedicle and variability of the pedicle origin.
- Identify and dissect out the SCIA and concomitant vein. Cutaneous veins may have to be used if there is no concomitant vein.
- Identify suitable arterial and venous sites of anastomosis in the hand, depending on the location of injury.

Flap Harvest

- Divide the vascular pedicle.

- Anastomose the SCIA to the appropriate vessels, depending on the location of the defect. An end-to-side anastomosis is recommended for the artery in order to not devascularize the recipient site. End-to-end anastomosis of veins is performed.
- The 12th thoracic nerve can now be repaired to an available nerve from the recipient hand if an innervated flap is planned (**TECH FIG 4**).
- Inset the flap to the recipient site using 3-0 nylon interrupted sutures.

TECH FIG 4• The SCIA and vein are anastomosed proximally, while a digital nerve or two can be repaired to a branch or branches of the 12th thoracic nerve.

Positioning	■ Place a bump under the ipsilateral hip to allow better visualization.
Technique	■ A full-thickness flap is raised. Thinning is done before inset. Leaving fat on the abdominal wall will make closure more difficult. ■ If the lateral femoral cutaneous nerve prohibits flap elevation, the surgeon can divide it to elevate the flap further and then repair the nerve. This nerve is usually not in the way when harvesting a pedicle flap because one does not need to skeletonize the pedicle medial to the sartorius fascia.
Postoperative care	■ The upper limb should be immobilized for 2 or 3 days, until the patient is comfortable with the position of the extremity and the flap. This is important to do prior to waking the patient up from anesthesia so the patient does not inadvertently reach for the endotracheal tube and damage the flap. ■ If the groin closure is very tight, patients may need to be immobilized with the hip in flexion. This can be done by placing pillows under the knee for a few days. ■ If there is marginal necrosis of the flap, wait for 2 to 3 days to let the necrosis demarcate as the initial postoperative swelling subsides. The patient should then return to the operating room for excision of necrotic portions and flap advancement and reinset. Waiting longer than 2 or 3 days risks further complications and failure of the flap. ■ The groin scar is closed under tension and will spread. Leave sutures in place until it is time for flap division, 3 to 4 weeks later.

POSTOPERATIVE CARE

- The open area near the pedicle is kept moist with bacitracin ointment twice daily and is covered with Xeroform gauze.
- Passive and active range of motion should start early under the supervision of a hand therapist.
- Compression bandages should be applied for bulky flaps.
- Surgery for thinning the flap should be delayed for at least 3 to 6 months.

OUTCOMES

- Arner and Moller⁶ retrospectively studied 44 pedicled groin flaps for coverage of hand and forearm soft tissue defects.

- Local complications (partial flap necrosis, infection, and seroma) occurred in 11 patients (25%).
- Defatting was subsequently required in 38 (86%) patients, and 4 patients (9%) required secondary revisions of donor sites.
- Goertz et al.² treated 85 patients with pedicled groin flaps and prospectively collected data on these patients. Forty-nine patients were later interviewed and examined, with mean follow-up of 9 years. Mean hospital stay was 29 days. Patients each required a mean of 4.6 operations (including thinning of the flap, deepening of the interdigital fold, stump, and flap revisions).
- One flap loss occurred.
- Of the 49 patients interviewed, 82% would undergo the procedure again.
- Mean Disabilities of the Arm, Shoulder, and Hand score was 23.
- The Vancouver Scar Scale showed close to normal height and vascularity of the flap (0.2 and 0.3, respectively), but pigmentation was slightly abnormal (0.8) and pliability was rated between “supple” and “yielding” (1.5).

COMPLICATIONS

- Flap necrosis
- Infection
- Shoulder and elbow stiffness
- Scarring

52 Free Anterolateral Thigh Flap

CHAPTER

John R. Lien and Kevin C. Chung

DEFINITION

- The anterolateral thigh flap is a versatile free flap that is often harvested as a fasciocutaneous flap, supplied by the descending branch of the lateral femoral circumflex artery (LFCA).
- It can be harvested also as a cutaneous or musculocutaneous flap with the vastus lateralis, with the option of an innervated flap with inclusion of the lateral femoral cutaneous nerve (LFCN).

ANATOMY

- The LFCA arises from the profunda femoris artery and divides into three branches (ascending, transverse, descending) deep to the sartorius and rectus femoris muscles (**FIG 1**).
- The descending branch of the LFCA courses distally along the medial border of the vastus lateralis, supplying perforators of the anterolateral thigh.
- Perforators supplying the anterolateral thigh are either of the following:
 - Musculocutaneous, which pass through the vastus lateralis muscle
 - Septocutaneous, which travel along the septum between the vastus lateralis and rectus femoris
- The LFCN passes under the inguinal ligament and pierces the deep fascia to innervate the skin of the anterolateral thigh.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with a history of peripheral vascular disease, active nicotine use, or generally poor health are not candidates for free tissue transfer.
- Obese patients may have a very thick flap and require primary thinning or

secondary debulking procedures.

- Examine the donor site for scarring and obtain a thorough history to include previous injury or surgery to the thigh.
- We do not routinely obtain preoperative angiography.

SURGICAL MANAGEMENT

- Anterolateral thigh flap is indicated for large soft tissue defects, though it is versatile and can be used for smaller defects if needed.
- A two-team approach can be used to decrease surgical time.
- Flap vascular pedicle can be long (12 cm), allowing for anastomosis outside of zone of injury, if necessary.
- Flap dimensions are generally limited to 35 cm long and 15 cm wide on a single dominant perforator, though multiple perforators are preferred in large flaps.
- Limiting the width of the flap to 8 cm generally permits primary donor-site closure.

Preoperative Planning

- Preoperative Doppler exam is used to confirm the presence of a perforator.
- If one is not detectable, consider the contralateral thigh or a different type of flap.

Positioning

- Supine with a bump under the right hemipelvis, or lateral decubitus position
- Drape out the entire lower limb for leg manipulation.
- Ensure the anterior superior iliac spine (ASIS) and patella are included in the operative field.

Approach

- A suprafascial approach to flap harvest achieves a thinner flap design, though it is more technically challenging.
- Subfascial flap harvest is technically easier to identify the vascular anatomy but will result in a bulkier flap.

FIG 1 • Anterolateral thigh flap anatomy.

TECHNIQUES

■ Flap Design

- Draw a line from the anterosuperior iliac spine (ASIS) to the superolateral border of the patella. This represents the intermuscular septum between the rectus femoris and vastus lateralis muscles (**TECH FIG 1**).
- Use a portable Doppler device to identify the perforator around the midpoint of this line.
 - 80% of perforators are found within 3 cm of this point.¹

- Design the flap dimensions based on the recipient site defect.
 - We generally design the perforator to be centrally located in the flap.
- For large flaps, we attempt to incorporate multiple perforators.

TECH FIG 1 • Flap design and identification of perforator. A line from the anterosuperior iliac spine (ASIS) to the superolateral patella (SLP) represents the intermuscular septum between rectus femoris and vastus lateralis. Perforators are identified with a Doppler ultrasound probe.

■ Flap Harvest

- Under loupe magnification, incise the medial margin of the designed flap.
- Suprafascial dissection
 - Deepen the medial incision to the deep fascia, and continue lateral dissection above the deep fascia.
 - Using tenotomy scissors, carefully separate the subcutaneous fat from underlying deep fascia. If possible, preserve cutaneous nerves overlying the fascia.
 - Continue dissection from medial to lateral and identify the marked perforator piercing through the fascia at the level of the intermuscular septum.
 - Incise the lateral margin of the flap and dissect from lateral to medial until the same perforator is visualized.
 - Leave a cuff of deep fascia around the perforator, and dissect retrograde toward its origin until adequate pedicle length and caliber is achieved.
- Septocutaneous perforators allow for uneventful dissection along the

intermuscular septum. However, the majority of the time perforators are musculocutaneous and pierce the muscle. To allow for safer dissection, the vastus lateralis is retracted laterally to visualize the descending LFCA, which can be dissected down to the perforator through the vastus lateralis muscle by separating the muscle fibers using scissors and bipolar cautery.

■ Subfascial dissection (**TECH FIG 2A**)

- Deepen the medial incision through the thigh fascia, exposing the rectus femoris muscle.
- Continue dissection laterally under the deep fascia until the intermuscular septum between rectus femoris and vastus lateralis is visualized.
- Retract the rectus femoris medially to visualize the descending branch of the lateral femoral circumflex artery (LFCA) and its perforating branches.
- The perforators may be musculocutaneous, traveling through the vastus lateralis, or septocutaneous, passing directly through the intermuscular septum.
- For septocutaneous vessels, dissection is performed from distal to proximal through the septum until adequate pedicle length and caliber is achieved. Leave a fascial cuff around the perforator (**TECH FIG 2B**).
- For musculocutaneous skin perforators, expose the point of exit from the muscle. Spread transversely over the vessel and divide the overlying muscle fibers. Ligate any intramuscular branches of the perforator, and continue retrograde dissection up to the descending LFCA until adequate pedicle length and caliber is achieved.
- If additional pedicle length is needed, continue retrograde dissection up the descending LFCA. During proximal dissection of the descending LFCA, take care to preserve the motor branches of the femoral nerve to the vastus lateralis.

TECH FIG 2 • A. Elevation of flap. Subfascial elevation allows for identification of the descending branch of the LCFA (D). Perforator is highlighted in yellow. RF, rectus femoris; VL, vastus lateralis. **B.** Completion of flap elevation. The perforator is dissected proximally, and the pedicle is dissected up the descending LFCA.

■ Flap Thinning

- If the flap is too bulky for the recipient site (hand/wrist), one can perform flap thinning at the time of harvest, as opposed to debulking at a later date. For beginners, we do not recommend primary flap thinning as inadvertent perforator injury can result in flap necrosis.
- Perform flap thinning after elevation but prior to transection of the vascular pedicle.
- Preserve a 3-cm radius cuff of full-thickness adipose tissue around the perforator.
- Thin the flap by removing the deep fat tissue, which is characterized by wide and flat lobules.
- Removing this deep layer of fat should result in flap thickness of 5 to 6 mm.

■ Donor-Site Closure

- Obtain adequate hemostasis of the donor site.
- Reapproximate vastus lateralis muscle edges in cases of intramuscular dissection.
- Primary closure is usually possible when the flap width is limited to 8 cm.
 - Place a suction drain to minimize risk of hematoma.
- If the donor-site width is more than 8 cm, the wound is unlikely to close primarily. Perform split-thickness skin grafting.

Flap dissection	■ Avoid unnecessary traction during flap elevation by dissecting around the perforator from the medial border and then lateral border, as opposed to elevating the entire flap from the medial border. ■ If the skin perforators are too small to safely perform an intramuscular dissection, consider the use of the operating microscope, or elevate the flap in a myocutaneous fashion by incorporating a cuff of muscle around the intramuscular pedicle. ■ Maintain the position of the flap during dissection. Traction on the perforator(s) from the weight of the flap may cause injury or vasospasm. ■ If there is concern for vasospasm, bathe perforators in topical lidocaine.
Flap thinning	■ Inexperienced surgeons should avoid aggressive one-stage flap thinning due to the risk of perforator injury and flap necrosis.
Hemostasis	■ Meticulous dissection during flap harvest is necessary particularly with musculocutaneous perforator dissection, as hasty division of muscular perforator branches will retract and be difficult to ligate.
Flap inset	■ Avoid twisting of the pedicle by preserving a cuff of fascia and allowing the pedicle to fall into its normal orientation before final inset.

POSTOPERATIVE CARE

- Avoid compressive bandages on the flap.
- Flaps are checked hourly with Doppler ultrasound for the first 48 hours postoperatively and then every 4 hours for the next 48 hours.
- The patient is kept hydrated with intravenous fluids and kept on thrombosis prophylaxis therapy (low molecular weight heparin) while hospitalized.
- Drain is removed once output is appropriate, typically less than 30 mL/d.
- If a skin graft was applied to the donor site, bed rest is instituted until the graft takes.
- Secondary debulking of the flap is delayed until 6 to 9 months postoperatively.

OUTCOMES

- Good results are reported with 96% overall survival rate of 672 flaps.²
- Donor-site morbidity is generally minimal. Anterolateral thigh numbness may result from sensory nerve division but can be avoided by careful preservation of suprafascial nerve branches.

COMPLICATIONS

- General complications related to free tissue transfer such as flap necrosis and hematoma are possible.
- Flap necrosis can occur from overaggressive flap thinning and perforator injury.

2. Wei FC, Jain V, Celik N, et al. Have we found an ideal soft tissue flap? An experience with 672 anterolateral thigh flaps. *Plast Reconstr Surg.* 2002;109:2219-2226.

53 Revascularization and CHAPTER Replantation of Digits

Mark Morris and Kevin C. Chung

DEFINITION

- Revascularization refers to the repair of injured structures and restoration of circulation to a digit that has been incompletely amputated. Restoration of vascularity to the incompletely severed digit is necessary to prevent necrosis.
- Replantation refers to the reattachment of a digit that has been completely amputated (**FIG 1**).
- Revision amputation refers to shortening a digit by debriding nonviable tissue and protruding bone in order to provide coverage of a digit that is not amenable to revascularization or replantation.

ANATOMY

- Each digit has a radial and ulnar proper digital artery. Each vessel is accompanied by a respective radial or ulnar proper digital nerve. Digital nerves are sensory only. In the digits, the artery is dorsal to the nerve (**FIG 2A**).
- There are three major palmar arches that arise from the digital arteries. The proximal, middle, and distal arches are located at the level of the C1 pulley, at the level of the C3 pulley, and just distal to the flexor digitorum profundus (FDP) insertion, respectively.
- Four palmar and four dorsal branches extend from each digital artery.
- The dorsal veins are larger than the palmar veins. Veins do not reliably travel with the arteries and nerves.
- Grayson ligament originates from the flexor tendon sheath and inserts on the skin. It lies palmar to the neurovascular bundle.
- Cleland ligament originates from the periosteum and inserts on the skin. It lies dorsal to the neurovascular bundle (**FIG 2B**).

- The flexor tendons travel within the flexor sheath. There is a series of five annular and three cruciform pulleys in which the flexor tendons pass through. The pulleys are discrete thickenings of the fibro-osseous sheath.
- Odd-numbered annular pulleys (A1, A3, A5) are located over the joints of the finger (metacarpophalangeal, proximal interphalangeal, and distal interphalangeal [DIP], respectively). Even-numbered annular pulleys (A2, A4) are located over the proximal and middle phalanges, respectively.
- The A2 and A4 pulleys are important in preventing bowstringing and should be preserved if possible.

FIG 1 • A–C. Complete amputation of the thumb. This injury required replantation. **D–F.** Partially amputated long and ring fingers. This injury required revascularization.

FIG 2 • A. Neurovascular anatomy of the digit. **B.** Axial cut of the digit, showing the relationship of Cleland and

Grayson ligaments to the neurovascular bundle. The digital nerve is palmar to the artery.

- The flexor digitorum superficialis (FDS) splits into two slips at Camper chiasm and inserts as two slips into the midportion of the middle phalanx.
- The FDP tendon passes between the two slips of FDS at Camper chiasm and inserts at the proximal base of the distal phalanx.
- The extensor digitorum communis (EDC) sends a tendon to each digit. The index finger also contains the extensor indicis proprius (EIP), and the small finger also contains the extensor digiti minimi (EDM). The EIP and EDM tendons are ulnar to their respective EDC tendon.

PATHOGENESIS

- Amputation can be caused by sharp or blunt dissection, crush injury, or avulsion injury.
- Sharp amputations have a narrow zone of injury and are thus better suited for replantation or revascularization (**FIG 3A**).
- Crush and avulsion injuries have a larger zone of injury, which may preclude replantation or revascularization (**FIG 3B**).

FIG 3 • A. Clean-cut amputation of the thumb. **B–D.** Crush-avulsion injury of the ring finger with a wide zone of injury secondary to the hand being caught in a gear mechanism, precluding successful replantation.

NATURAL HISTORY

- Mean survival rate after replantation is 86% reported by highly experienced surgeons and hospitals.¹
- Clean-cut amputations have a better survival rate (92%) than crush-cut (80%) or crush-avulsion injuries (75%).
- Mean two-point discrimination after replantation is 7 mm.
- Ninety-eight percent of patients are able to return to work after digit replantation.¹

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history must include the mechanism and timing of injury. Crush injuries may preclude replantation depending on the degree of tissue damage.
- Ischemia time and method of transport must be evaluated. In general, warm ischemia time of less than 6 hours and cold ischemia time of less than 12 hours are desired for replantation.
- Delayed replantation has been shown to have success, however. In a study of delayed and suspended replantation of digits and hands, Woo et al.² studied 28 digital and 4 hand amputations that underwent delayed or suspended amputation (mean cold ischemic time 15 hours 48 minutes). In this series, 24 of 28 digits and all 4 hands survived (88% survival rate). Case reports exist with successful replantation after warm ischemia times of 42 hours and cold ischemia times of 94 hours.^{3,4}
- Transportation method of an amputated digit is important. The digit should not be placed directly on ice but should rather be wrapped in gauze moistened with normal saline or lactated Ringer's and placed into a plastic bag, which is then placed in an ice slush.
- A psychological and mental health history is important, as patients will require significant compliance with rehabilitation protocols.
- Medical history including diabetes mellitus, peripheral vascular disease, hypercoagulability, or smoking is not a contraindication to revascularization or replantation but will affect the healing potential of the digit(s) and must be discussed with the patient.
- The surgeon must examine the extremity to assess the number of digits injured, vascularity and sensation of partially amputated digits, wound contamination, and type of injury sustained.
- Several classifications exist for fingertip amputations. Two commonly used classifications are by Allen and Tamai.
 - Allen⁵ (**FIG 4A**)
 - Type I: Only the pulp of the finger is involved. No suitable vessel for anastomosis.
 - Type II: Pulp and nail loss. Preserves half of the nail bed. No dorsal vein available for anastomosis.
 - Type III: Partial loss of the distal phalanx in addition to pulp and nail loss. High incidence of hook-nail deformity if nail bed is not ablated.

- Type IV: Amputation proximal to nail fold. Dorsal vein usually available for anastomosis.
- Tamai⁶ (**FIG 4B**)
 - Zone 1: Fingertip to the base of the nail
 - Zone 2: Between the base of the nail and the DIP joint

FIG 4 • Classification of fingertip amputations. **A.** Allen classification. **B.** Tamai classification.

- Red line sign—a red streak along the lateral border of a digit suggests hemorrhage from an avulsed branch of the digital artery after a traction injury.
- Ribbon sign—coiling of a digital artery at the amputation site. This also results from a traction injury (**FIG 5**). If replantation or revascularization is attempted, vein grafting will be required.

IMAGING

- Standard radiographs of the injured extremity and the amputated parts should be performed, in order to better understand the extent of injury and to plan fixation (**FIG 6**).

NONOPERATIVE MANAGEMENT

- There is no role for nonoperative management in digit amputations or dysvascular partial amputations.
- Occasionally, revision amputation can be performed in the emergency department, but this is often better done in the operating room with appropriate anesthesia, sterile conditions, lighting, and equipment.

FIG 5 • The red line sign and ribbon sign are both signs of artery avulsion from a traction injury. If these signs are present, a vein graft should be attempted rather than direct repair, as the vessel walls have been injured.

FIG 6 • A,B. Radiographs of a patient who sustained a crush injury to the right hand, with multiple devascularized digits.

SURGICAL MANAGEMENT

- Patients undergoing revascularization or replantation should also be consented for possible revision amputation, as a final decision to revascularize or replant a digit will be made after all structures are carefully evaluated in the operating room.
- Indications for replantation:
 - Thumb
 - Multiple digits
 - Partial hand (through-palm amputation)
 - Through wrist or forearm
 - Almost any part in a child
 - Individual digit distal to the FDS tendon
- Contraindications to replantation:
 - Severely crushed or mangled digit
 - Multilevel amputation
 - Concomitant life-threatening injuries

- Severely atherosclerotic vessels
- Patients who are unable to comply with a postoperative rehabilitation program
- Prolonged warm ischemia time (relative; see discussion in history and physical section)
- Individual finger amputation in an adult at a level proximal to the FDS insertion (controversial; limited function in a replanted digit at this level may negatively affect overall hand function)
- The sequence of repair is as follows:
 - Debridement and identification of injured and intact structures. Place vascular clips on the arteries. This will help with later identification. In addition, if the tourniquet needs to be let down prior to arterial repair, the field will remain dry.
 - Bone shortening and/or fixation
 - Extensor tendon repair
 - Flexor tendon repair
 - Vein repair while still under tourniquet. This is a deviation from the classic teaching (arteries before veins), because many surgeons find it easier to repair veins in a bloodless field.
 - Arterial repair
 - Nerve repair
 - Skin closure/coverage

Preoperative Planning

- Antibiotics and tetanus prophylaxis are given as soon as possible upon presentation to the emergency department.
- Regional anesthesia provides increased peripheral vasodilation.
- Amputated digits are transported to the operating room, and initial preparation begins as soon as possible.
 - This can be done while the anesthesia team is evaluating the patient and inducing anesthesia.
 - The surgical team can use a back table to start dissecting the amputated part to identify all the parts that will be connected.

Positioning

- The patient is placed supine on the operating table.
- The operative extremity is placed on a hand table.

- A brachial tourniquet is applied.

Approach

- Debridement and careful identification of structures is the key first step.
 - Keep track of each structure as it is identified by writing a count sheet or having the circulating nurse do so.
 - Each structure is tagged with a suture or a clip for future identification.
- Duration of surgery is decreased by repairing “structure by structure” rather than “digit by digit.” Repair the same structure on each digit rather than completing all aspects of replantation on one digit at a time.
- A two-team approach can be used to save time. One team prepares the amputated digit(s) while the other team prepares the patient.
- Vein, artery, and nerve repairs are performed under the operating microscope. Microsurgical instruments are used.
- Never discard amputated parts until the surgery is over. Amputated parts are a useful source of autologous materials when needed such as nerve grafts, vascularized skin flap, tendons, bone, and vessels.

TECHNIQUES

■ Preparation of Amputated Digits and Stumps

- The amputated digits are brought to the operating room as soon as possible. One team will prepare the amputated digits while the other team prepares the patient.
- The parts are cleaned on a sterile prep table.
- Contaminated edges of the amputated digits and stumps are debrided, and arteries, nerves, and veins are identified.
 - Vascular clamps can be placed on arteries at this time for identification and later hemostasis.
- Midaxial incisions are made on the radial and ulnar sides of the digit to further expose neurovascular structures (**TECH FIG 1**).
- Flexor and extensor tendons are identified.
- Bone is shortened with a rongeur or a microsagittal saw to facilitate the vessel repair to obviate the use of vein graft and nerve graft. Bone should be

shortened if much tissue debridement was required. Shortening will facilitate tension-free anastomosis and skin closure.

- Amputated digits should be kept cool until they are ready to be replanted.

TECH FIG 1 • A,B. Midlateral incisions are made on either side of the amputation to assist in visualization, identification, and repair of neurovascular structures.

■ Bone Fixation

- Bone fixation can be accomplished using many different methods, including longitudinal K-wires, crossed K-wires, intraosseous wiring, tension band, intramedullary screws, and plate and screws.
 - Parallel longitudinal K-wires are fast and easy and have good success rates.
- In the amputated digit, two 0.045 K-wires are placed longitudinally into the bone in retrograde fashion.
 - The wire should exit the tip of the digit just palmar to the nail.
 - Advance the wire until just the tip is showing through the proximal end of the bone, ready to be advanced into the bone from the stump.
- Align the bones from the amputated part of the digit and its stump.
 - Take care to restore proper rotational alignment.
 - Advance the K-wires into the proximal bone and confirm location with

radiographs (**TECH FIG 2**).

TECH FIG 2 • A–C. Parallel K-wire fixation was used in this case of thumb replantation.

■ Tendon Repair

- Extensor tendons are repaired with two 4-0 nonabsorbable sutures in horizontal mattress fashion.
- In-depth discussion of flexor tendon repair can be found in a separate chapter in this text.
 - We typically use a looped 4-0 Supramid suture to complete a six-strand repair of flexor tendons, followed by a running epitendinous 6-0 Prolene suture.
 - Both flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) can be repaired; however, it is not necessary to repair the FDS if this will impede tendon gliding if the FDS is shredded and too traumatized.
 - If the amputation is distal to the FDS insertion, extensor and flexor tendon repair can be disregarded and the distal interphalangeal (DIP) joint can be fused.

■ Vein Repair

- Ideally, two veins are repaired for each artery that is repaired.
 - Research has shown a significantly better survival rate after two venous anastomoses per digit compared with one. However, there was no difference in this study between none and one vein repaired.⁷
 - Another study also showed no difference in survival rates between distal digit replantations with and without venous anastomosis.⁸
 - We recommend venous repair whenever possible, despite the findings of the later study.
 - Venous repair prior to arterial repair allows for this most difficult task to be performed in a bloodless field and perhaps doing this critical procedure when the surgeon is still fresh, rather than at the end of the case when fatigue sets in.
 - Because the veins are thin, the surgeon needs to take minimal bites of the vessel wall to prevent folding in of the adventitia. Side branches can be clipped to lengthen the vein so that it can reach to the other end.
 - Irrigate the lumen of the vein with heparinized saline using a 30-gauge blunt-tipped needle to keep it open.
 - Fewer sutures are required for venous repair than arterial repair because of the low-pressure flow.
 - If vein grafts are required, appropriate-sized donor grafts (1–2 mm) can be harvested from the volar wrist.
-

■ Artery Repair

- Arteries have been previously clamped when structures were identified earlier. The tourniquet can be let down at this time. Vascular clamps will control bleeding.
- Both digital arteries should be repaired when possible, to maximize survival rates.
- Damaged ends of arteries are sharply debrided back to normal intima until one gets a robust spurt from the artery, which indicates suitable resection of the traumatized vessel.
- Vein grafts are used if there is any defect after debridement.
 - Vein grafts must be rotated 180 degrees with respect to flow, because of the valves that are present.
 - For proper size match, vein graft from the volar wrist is used.

- For vein grafting in the palm, vein graft from the forearm has suitable size match.
- Artery ends are approximated in a tension-free manner, but without redundancy of the vein graft. This can be done with vascular approximating clamps (**TECH FIG 3**).
- A microsurgical dilator is used to dilate the arterial lumen and assess blood flow by transiently releasing the vascular clamp on the stump side.
- If there is inadequate blood flow, evaluate for reversible causes such as vasospasm, cold, acidosis, hypotension/hypovolemia, or mechanical constriction.
- Vasospasm can be treated by irrigating with papaverine solution (diluted 1:20 with normal saline).
- Irrigate the lumen with heparinized saline using a 30-gauge blunt-tipped needle.
- We recommend the use of a background to help with visualization.
- A bolus of 5000 units of intravenous heparin is given prior to anastomosis. A heparin drip is then initiated at 1000 units per hour.
- Suture size depends on the size of the vessel being repaired. In general, 11-0 nylon suture is used in the distal digit, 10-0 nylon suture is used in the proximal digit, and 9-0 nylon suture can be used in the palm.
- Interrupted sutures are placed circumferentially, with care to avoid capturing the back wall with the needle.
- Each bite of the needle should be 1 to 2 times the thickness of the arterial wall.
- Leave one limb of each of the initial sutures long. The suture ends can be used later to manipulate the vessel in a minimally traumatic manner.
- Release the vascular clamps and observe for pulsations and a water-tight seal.

TECH FIG 3 • A vascular approximating clamp is used to bring the arterial ends together in a tension-free manner.

■ Nerve Repair

- The severed ends of the nerve are sharply cut using microsurgical scissors or a no. 11 blade against a wooden tongue depressor.
- Nerve ends are approximated in a tension-free manner.
 - If tension-free repair is not possible, primary nerve grafting is performed. The medial or lateral antebrachial cutaneous nerves can be harvested from the ipsilateral extremity.
 - Alternatively, other amputated digits that are not candidates for replantation can be used to provide nerve graft of appropriate caliber.
- Fascicles are aligned and epineural repair is performed using three or four 9-0 or 10-0 nylon sutures.

■ Closure

- Obtain hemostasis prior to skin closure. Hematoma will place pressure on vascular repairs and can result in failure of the replant.
- Interrupted 4-0 nylon sutures are used to close the skin (**TECH FIG 4**). Take

care to avoid constriction of underlying structures.

- Skin grafts or flaps are used as needed.

TECH FIG 4 • Same patient as in **FIG 1**. Postoperative images after thumb replantation (**A-C**) and long and ring finger revascularization (**D,E**).

PEARLS AND PITFALLS

Preparation

- Make a tally sheet for the structures that are injured in each digit as you debride and identify structures. This will help the case go smoother and will help with dictation postoperatively.
- Prioritize the functional goals of the patient for replantation. If multiple digits are amputated and some are not replantable, the salvageable digits should be placed in the most functional position—

	ie, if the thumb is not salvageable, replant a finger in the thumb's position.
Technique	■ Duration of surgery is decreased by repairing “structure by structure” rather than “digit by digit.” Repair the same structure on each digit rather than completing all aspects of replantation on one digit at a time. ■ All anastomoses should be tension-free. Bone shortening or vein grafting should be performed to accomplish this.
Treatment of venous congestion with leeches	■ If an inadequate number or quality of venous anastomoses are performed, venous congestion may occur in the digit. If this occurs, the nail can be removed and medical leeches (<i>Hirudo medicinalis</i>) can be placed postoperatively. They should be changed every few hours and continued for 7 days. ■ Patients should be treated with a third-generation cephalosporin while leeches are in use as prophylaxis against <i>Aeromonas hydrophila</i>, which is a symbiotic gram-negative rod in the leech gut.

POSTOPERATIVE CARE

- The postoperative dressing should not be circumferential or constricting.
 - Xeroform gauze is applied to the incisions.
 - A well-padded plaster splint is applied, with the tips of the digits exposed to monitor for vascular status.
 - Temperature probes or pulse oximeters can be applied to the fingertips for monitoring.
- The splint is changed after 1 or 2 days in case a blood cast forms. If there is excessive bleeding, the clotted blood on the dressings and splint will solidify and cause circumferential constriction.
- Color, warmth, and capillary refill are monitored by the surgeon and nursing staff.
- The patient's room should be kept above 72°F (22°C). We alternatively use a Bair hugger to cover the extremity and keep it warm.
- Bed rest is maintained for at least 2 or 3 days, or longer if the vascular status is tenuous.
- No caffeine, chocolate, or nicotine is permitted.
- A bolus of 50 mL Dextran 40 is given in the operating room, followed by a maintained rate of 20 mL/h while the patient is still hospitalized.
- The patient is maintained on low molecular weight heparin or unfractionated heparin for 5 days. Low molecular weight heparin has been reported to be as

effective as unfractionated heparin but with fewer adverse effects.⁹

- Aspirin 325 mg daily is started postoperatively and continued for 6 weeks.
- Anxiolytics can be provided to the patient so he or she does not unintentionally harm the repair secondary to anxiety.
- Thorazine 25 mg orally every 8 hours can be used as both an anxiolytic and a peripheral vasodilator.

OUTCOMES

- Sebastin and Chung¹ performed a systematic review of the outcomes of replantation of distal digital amputation (**FIG 7**). Thirty studies were included in the review.
- Mean survival rate after replantation was 86%.

FIG 7 • **A,B.** Five months after bilateral long and ring finger revascularization. **C–E.** Ten months after left thumb replantation.

- There was no difference in survival of replanted digits based on Tamai classification of zone I or zone II.
- Clean-cut amputations had significantly better survival rates than crushed amputations (92% for clean-cut, 80% for crush-cut, and 75% for crush-avulsion).

- Repairing a vein improved survival in both zone I and II replantation (zone I with venous repair 92% survival vs 83% without repair. Zone II with venous repair 88% survival vs 78% without repair).
- Mean two-point discrimination after replantation was 7 mm.
- Ninety-eight percent of patients were able to return to work.
- Yu et al.¹⁰ performed a meta-analysis to investigate nonsurgical factors associated with survival rates of digital replantation.
- Ischemia time (over or under 12 hours) had no significant correlation with survival rate.
- Clean-cut injuries had better outcomes than crush and avulsion injuries.
- The thumb had a better chance of survival than did the small finger (OR 2.09), while there were no significant differences between other digits.
- The chance of survival was higher in digits that were transported cold when compared to those transported at room temperature (OR 4.89).

COMPLICATIONS

- Pulp atrophy (14%)
- Nail deformity (24%)
- Failure of replant (14%)
- Venous congestion
- Infection
- Cold intolerance—Almost all patients experience this. Cold intolerance is expected to improve over the first 2 years but may never resolve.
- Stiffness—Tenolysis should be delayed for at minimum 3 months postreplantation.
- Malunion
- Nonunion

54 Digital Artery Sympathectomy

CHAPTER

John R. Lien and Kevin C. Chung

DEFINITION

- Raynaud disease (RD) is characterized by cold hypersensitivity and color changes to digits secondary to an exaggerated vasoconstrictive response to cold temperature, emotional stress, or trauma.
 - There is no underlying associated cause for these vasospastic events in RD.
- Raynaud phenomenon (RP) occurs in patients with a diagnosis of underlying collagen vascular disease such as scleroderma.

ANATOMY

- The superficial palmar arch is the continuation of the ulnar artery in the palm. The common digital arteries arise from this palmar arch (**FIG 1**).
- The common digital nerves course alongside the common digital arteries, supplying sympathetic fibers to the adventitial layer of the arteries.

FIG 1 • Palmar neurovascular anatomy. The ulnar artery provides dominant flow to the superficial palmar arch (deep palmar arch not shown).

PATHOGENESIS

- The function of arterial smooth muscle is to constrict and decrease blood flow.
- Vasospastic disorders are characterized by reversible changes in flow, whereas occlusive disorders involve decreased flow unrelated to vasoconstriction.
- In occlusive disorders such as scleroderma, ischemia of the digit may result from inadequate collateral vessels or inadequate flow through collaterals secondary to vasospasm.

NATURAL HISTORY

- Natural history of the digital ischemia is largely dictated by the underlying cause.
- Patients with underlying mixed connective tissue disorder often have worsening digital symptoms/ischemia as their disease progresses. This can lead to trophic changes such as ulcers and gangrene.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically report a triphasic color change (white, blue, red) in both RD and RP.
- Obtain a thorough rheumatologic history. Patients with suspected primary RD may have unrecognized mixed connective tissue disorders.
- Frequency and severity of ischemic episodes, extent of cold sensitivity, numbness, pain
- Association of symptoms with emotional changes
- Active nicotine use is a contraindication to surgical intervention.
- Allen testing should be performed to assess patency of palmar arches.
- Note trophic changes such as ulcers and gangrene.
- Assess for laterality; focal unilateral symptoms may be concerning for embolic disease.

IMAGING

- Angiography provides excellent anatomic detail and structural information. Vasospastic contribution to ischemia can be enhanced by the use of intra-arterial vasodilators. If the patient fails medical management, we obtain this study as part of our preoperative evaluation.
- Noninvasive vascular studies
 - Digital brachial index (DBI) values assess total flow to the digit. DBI less than 0.7 indicates abnormal flow.
 - Doppler sonography
 - Digital plethysmography (pulse volume recordings) can differentiate vasospastic from vaso-occlusive disease, particularly with cold stress testing.

DIFFERENTIAL DIAGNOSIS

- Primary Raynaud disease
- Secondary Raynaud phenomenon
 - Rheumatic disease, eg, scleroderma, systemic lupus erythematosus
 - Hematologic disorder

- Atherosclerotic disease
- Embolic disease

NONOPERATIVE MANAGEMENT

- Lifestyle modification
 - Tobacco cessation
 - Avoidance of cold environment (gloves, warmer climate in winter)
- Biofeedback therapy
- Medical management¹
 - Calcium channel blocker such as nifedipine is a first-line treatment.
 - Phosphodiesterase-5 inhibitors (sildenafil, tadalafil, vardenafil), topical nitroglycerin, angiotensin-receptor antagonist (losartan), and selective serotonin reuptake inhibitors (fluoxetine) are other among second-line medications.
- There may be a role for botulinum toxin type A injection, but larger controlled trials are necessary to establish its effectiveness.²

SURGICAL MANAGEMENT

- Indications for digital sympathectomy include digital ischemic pain and/or trophic changes refractory to medical management. This commonly includes patients with autoimmune disorders such as scleroderma. Often, this is a surgery of last resort in patients with persistent and unrelenting ischemic pain.
- Patients with primary RD often respond to medical management. We rarely offer surgical sympathectomy to these patients.
- We do not offer this surgery to active smokers.
- Contraindication to sympathectomy includes severe primary atherosclerotic occlusive disease.
 - For the sympathectomy to produce increased flow to the digit, there must be a reversible vasospastic component to either the digital artery or its distal collaterals.

Preoperative Planning

- If preoperative studies demonstrate vasospastic disease with secondary occlusion of the radial/ulnar artery or palmar arch, we consider arterial reconstruction with vein grafting.

Positioning

- Supine with hand table and arm tourniquet

Approach

- For single-digit sympathectomy, we perform an extensile Bruner zigzag incision over the ray of the digit in the distal palm.
- In the setting of multiple-digit sympathectomies, we perform a transverse oblique incision at the palmar crease (**FIG 2**).

FIG 2 • Incision for multiple-digit artery sympathectomy (A) and single-digit sympathectomy (B).

TECHNIQUES

■ Exposure

- Under tourniquet control, perform a Bruner incision overlying the appropriate ray in the distal half of the palm (or transverse oblique incision for multiple-digit sympathectomies; **TECH FIG 1A**).
- Elevate full-thickness skin flaps and expose the superficial palmar arch proximally.
- Identify the origins of the common digital arteries supplying the radial and ulnar aspects of the appropriate finger.

- Dissect the common digital arteries and nerves from proximal to distal, ensuring exposure of 2 to 3 cm of vessel length (**TECH FIG 1B**).

TECH FIG 1 • A. Brunner incision is marked. Trophic changes to the index and middle fingertips can be seen in this patient with scleroderma and persistent middle finger pain. **B.** Exposure of radial and ulnar digital neurovascular bundles to middle finger.

■ Sympathectomy

- Under microscope magnification, systematically strip the common digital artery adventitia for 2 to 3 cm.
- While doing this, any communicating sympathetic nerve branches from the digital nerve to the artery should be divided (**TECH FIG 2**).
- Take care to avoid injury to the digital artery. Small arterial branches should be tied off using microsurgical technique.
- Release the tourniquet and ensure hemostasis.
- Loosely close the wound.

TECH FIG 2 • Microscope view of neurovascular bundles after sympathectomy.

PEARLS AND PITFALLS

Technique

- Avoid iatrogenic arterial injury or vasospasm by minimizing trauma to the digital artery. Use microsurgical technique during adventitial stripping.

Arterial reconstruction

- When possible, consider arterial reconstruction if there is inadequate collateral circulation with proximal occlusion. Sympathectomy alone can be performed as a palliative salvage procedure if occlusive disease is nonreconstructible.

POSTOPERATIVE CARE

- Patient is placed in a volar forearm-based splint postoperatively.
- At the first 2-week postoperative visit, sutures are removed and range of motion is encouraged.

OUTCOMES

- Reported outcomes on ulcer healing and pain improvement are heterogeneous due to small case volume and lack of controlled studies.³
- In general, better outcomes in terms of ulcer healing are noted in patients who have underlying autoimmune disease as compared to severe atherosclerotic disease.⁴
- Twenty-eight of forty-two digits in patients with autoimmune disease had complete ulcer healing or decrease in number of ulcers. Two of seventeen digits had healing in the atherosclerotic group.
- At a minimum of 23 months of follow-up, 26% (11 of 42) of digits in the autoimmune disease group ultimately required amputation, whereas 59% (10 of 17) in the atherosclerotic group ultimately required amputation.

COMPLICATIONS

- Persistent ischemic pain
- Persistent wound/ulcers necessitating amputation
- Iatrogenic arterial injury/thrombosis

Ulnar Artery to Superficial Arch Bypass With a Vein Graft for Ulnar Artery Thrombosis

55

CHAPTER

Mark Morris and Kevin C. Chung

DEFINITION

- Hypothenar hammer syndrome refers to post-traumatic digital ischemia secondary to thrombosis of the ulnar artery.
- The ulnar artery at Guyon canal and the proximal superficial arch are the most common sites of occlusion.
- “Critical” vascular injuries result in tissue death without intervention.
- “Noncritical” vascular injuries occur when an artery is damaged, but collateral circulation is adequate and prevents tissue necrosis.
- A “complete” superficial or deep palmar arch is defined as having a significant connection to a branch from another independent arterial limb such that it provides branches to all digits. The superficial arch is complete in 78.5% of extremities, and the deep arch is complete in 98.5% of extremities.¹

ANATOMY

- The major blood supply to the hand is from the superficial palmar arch, which is a continuation of the ulnar artery, and the deep palmar arch, which is a continuation of the radial artery (**FIG 1**).
- A median artery may also be present.
- The radial artery bifurcates into dorsal and volar branches at the level of the radial styloid. The dorsal branch traverses the floor of the snuffbox and passes through the first dorsal interosseous muscle, diving volar and becoming the primary contributor to the deep palmar arch. The volar branch contributes to

the superficial arch.

- The ulnar artery bifurcates into deep and superficial branches at the level of the wrist. The deep branch anastomoses with the deep palmar arch, whereas the superficial branch terminates as the superficial palmar arch.
- The radial artery and deep palmar arch provide the dominant blood flow to three or more digits in 57% of normal extremities, whereas the ulnar artery and superficial arch provide dominant flow to three or more digits in 21.5%, and there is equal contribution from radial and ulnar arteries in 21.5% of extremities.²
- Deep palmar arch runs deep to the flexor tendons at the level of the base of the metacarpals, 1 cm proximal to the superficial arch.
- Superficial palmar arch is located at Kaplan line (line drawn across the palm from the first web space parallel to the proximal palmar crease toward the hook of the hamate), 1 cm distal to the deep palmar arch.
- The deep and superficial arches provide common digital arteries to the second, third, and fourth web spaces at the mid-metacarpal level. These then divide into proper digital arteries at the level of the MCP joint.
- A less significant dorsal circulation also exists, receiving contributions from dorsal carpal branches of the radial and ulnar arteries.

PATHOGENESIS

- A single or more likely repetitive impact to the hypothenar eminence leads to ulnar artery thrombosis or aneurysm (**FIG 2**).
- Ulnar artery thrombosis has been reported in patients participating in baseball, golf, weight lifting, karate, mountain biking, volleyball, and overenthusiastic clapping by fans. At-risk occupations are those requiring vibrating tools such as carpentry, construction, machine operators, and mechanics.
- The hook of the hamate acts as an anvil against which the ulnar artery is crushed.

FIG 1 • Vascular anatomy of the hand. The superficial palmar arch is supplied by the ulnar artery. The deep palmar arch is supplied by the radial artery.

FIG 2 • The ulnar artery travels in Guyon canal with the ulnar nerve. **A,B.** The floor of the canal is made by the transverse carpal ligament, and the roof is made by the volar carpal ligament. The close proximity of the artery leaves it susceptible to impact into the hook of the

hamate.

- Repetitive trauma can lead to direct intimal damage, which leads to thrombosis, or periadventitial thickening of the artery that constricts the vessel and obstructs flow.
- Disruption of the internal elastic lamina of the artery leads to aneurysm, which predisposes to mural thrombosis, complete occlusion, and distal thrombotic emboli (**FIG 3**).
- Arterial occlusion or distal emboli can lead to ulceration, gangrene, and necrosis of digits.

FIG 3 • Repetitive impact to the ulnar artery leads to either periadventitial thickening or disruption of internal elastic lamina. Both conditions leave the artery prone to thrombosis.

NATURAL HISTORY

- Depending on the severity of occlusion and quality of flow from the deep arch, the natural history will vary.
- The long, ring, and small fingers may develop cyanosis, pallor, splinter hemorrhages, ulcerations, atrophy of distal finger pads, or even necrosis of digits.
- Most patients will develop cold intolerance.
- Most patients will have persistent symptoms even after revascularization, although with decreased frequency and severity.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with post-traumatic ulnar artery thrombosis are predominantly male and present with unilateral hand and digit ischemia.
- The dominant hand is most commonly affected, although bilateral cases have been reported.
- History of interest includes vascular disease, smoking, manual labor, use of palm as a hammer, use of vibrating tools.
- Symptoms include pain, numbness or tingling, cold intolerance, and weakness in the ulnar nerve distribution.
- Signs on physical exam include pallor, cyanosis/mottling, a palpable hypothenar mass (if an aneurysm is present), atrophy of distal finger pads, splinter hemorrhages, ulcerations, and gangrene of the long, ring, and small fingers (**FIG 4**).
- Ischemic problems of the thumb have never been described with post-traumatic ulnar artery thrombosis. If present, a different diagnosis should be considered.
- Radial and ulnar pulses are palpated and examined by Doppler probe if not palpable.
- Doppler can also be used to assess the palmar arch and radial and ulnar digital arteries to each finger.

FIG 4 • Signs of ulnar artery thrombosis—pulp atrophy, ulcerations, cyanosis, pallor, palpable pulsatile mass in the hypothenar eminence. The thumb should appear normal. The number of affected digits will vary depending on perfusion from the radial artery and deep arch.

- A modified Allen test should be performed to assess blood flow to the hand from the radial and ulnar arteries independently (**FIG 5**):
 - One hand is examined at a time.
 - The patient is asked to clench the fist tightly for one minute.
 - Pressure is applied over the radial and ulnar arteries so as to occlude both.

FIG 5 • Allen test in a patient with ulnar artery thrombosis. The examiner occludes both the ulnar and radial arteries and the hand is white as a result of a lack of perfusion. When pressure is released from the ulnar artery, the hand remains white because of an occluded ulnar artery.

- The patient opens the fingers. Pallor should be observed at this time.
- Pressure is released from the ulnar artery, and color should return if ulnar artery supply to the hand is sufficient. Pallor will remain if there is insufficient ulnar flow. The radial artery is then released and color should return to the entire hand if the deep arch is complete.
- The test is repeated, but with pressure being released from the radial artery first.
- Several questionnaires exist to assess symptoms and disability related to ischemia of the hand:
 - The Levine-Katz questionnaire assesses pain, symptoms of dysesthesia, and hand function.³

- The McCabe Cold Sensitivity Test assesses cold sensitivity and associated symptoms.⁴
- The Cold Intolerance Symptom Severity questionnaire adds questions and assessments that are not addressed by the McCabe test.⁵

IMAGING

- Noninvasive studies are done first.
 - Standard PA, lateral, and oblique radiography of the hand are performed to evaluate bony architecture as well as vascular calcifications.
 - Pulse volume recording measures the volume of arterial blood flow. Inadequate flow to the hand and digits can be detected by comparing proximal and distal blood flow. The severity and general location of occlusive disease can be determined by pulse volume recording.
 - Digital brachial index (DBI) compares digital blood pressure to contralateral brachial blood pressure in order to quantify perfusion to the hand and digits. The normal range for DBI is 0.75 to 0.97. Values equal or less than 0.7 signify inadequate perfusion.
 - Doppler or vascular duplex ultrasound can be used to evaluate flow. This provides audible and color-coded visual information about flow. Duplex can provide information about flow abnormalities, structural abnormalities of vessels, presence of thrombus, and aneurysm. The weakness of this study is the lack of standardization and operator-dependent nature of the study.
- Invasive tests can be performed if noninvasive tests are abnormal.
 - Computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) are minimally invasive tests that require venous access for the administration of contrast dye. Both hands can be evaluated simultaneously for comparative assessment. Anatomic details provided by both tests are similar, but both have advantages and disadvantages. MRA contrast is less nephrotoxic than CTA contrast. MRA is susceptible to motion artifact and cannot be used in patients with certain metallic implants or claustrophobia. MRA is significantly more expensive than CTA, although both are cheaper than conventional angiography.
 - Conventional angiography/arteriography is the standard for evaluation of ulnar artery thrombosis (**FIG 6**). Angiography shows the surgeon the features of ulnar artery thrombosis including a corkscrew appearance of the ulnar artery, alternation of stenosis and dilation, aneurysm formation, occlusion of the ulnar artery at the hook of the hamate, or occlusion of the superficial

palmar arch or digital arteries with a normal proximal ulnar artery. Conventional angiography requires arterial access and contrast dye administration and has risks of bleeding, hematoma, thrombosis, pseudoaneurysm, allergic reaction, renal toxicity, and a four-fold higher dose of radiation than CTA. Conventional angiography is contraindicated in patients with renal insufficiency.

FIG 6 • Arteriogram demonstrating absent flow from the ulnar artery into the hand.

DIFFERENTIAL DIAGNOSIS

- Hypothenar hammer syndrome (post-traumatic ulnar artery thrombosis)
- Raynaud disease
- Malignancy, vascular tumors

- Pseudoaneurysm
- Trauma, iatrogenic injury
- Buerger disease
- Arteritis
- Peripheral vascular disease (atherosclerosis)
- Connective tissue disorders (scleroderma, systemic lupus erythematosus)

NONOPERATIVE MANAGEMENT

- Nonoperative treatment can be considered for patients without impending digital loss.
- Smoking cessation
- Medications can be used to decrease sympathetic tone and vasospasm—calcium channel blockers, α -blockers, β -blockers, steroids, prostaglandins, and prostacyclin have been described.
- Antiplatelet or anticoagulant agents can be used in patients with thrombosis and embolic disease.
- Intra-arterial thrombolytics can be percutaneously directed to the site of ulnar artery thrombosis. Success of this procedure is limited, with a high complication rate.
- Digital sympathectomy with botulinum toxin A can be performed, with low morbidity.

SURGICAL MANAGEMENT

- Surgical intervention is indicated in patients who have failed medical management or those with impending digital necrosis.
- Surgical options include open sympathectomy, exploration and ligation of the diseased segment of artery, exploration and primary repair of the ulnar artery, or exploration and revascularization by arterial bypass.

Preoperative Planning

- Preoperative imaging (eg, CTA, MRA, angiogram) is reviewed to determine the site of bypass.
- Donor vessels are identified and marked.
- Venous or arterial grafts can be used.
 - Vein interpositional grafts must be reversed because of the presence of valves.
 - Veins are typically more expendable than arteries and provide longer grafts.

- Arterial grafts are easier to match in size. They are less flimsy and do not need to be reversed.
- Table 1 covers donor grafts available for ulnar artery bypass.
- An operating microscope and microsurgical instruments are used for microvascular anastomosis.

Table 1 Donor Grafts for Ulnar Artery Bypass

Graft	Length (cm)	Comments
Vein		
Greater saphenous	50–85	Found superficially, easier dissection, but decreased long-term patency rates compared to arterial grafts. Greater saphenous and basilic have poor size match to the ulnar artery at the wrist.
Lesser saphenous	35–60	
Forearm	14–20	
Basilic/cephalic	15–30	
Dorsum of foot	5–8	
Artery		
Subscapular	2–4	Short pedicle length
Superficial inferior epigastric	6–10	Abdominal bulge
Deep inferior epigastric	10–12	Abdominal bulge
Thoracodorsal	11–14	Dissection in axilla
Lateral circumflex femoral	10–18	Deep, variable anatomy

Positioning

- The patient is placed supine on the operating table with a hand table for the operative extremity.
- A brachial tourniquet is placed.
- Depending on the graft to be used, another extremity (usually a lower extremity) may need to be prepped and another tourniquet placed.

Approach

- The affected segment of artery will be excised. The surgeon must first obtain

proximal and distal control of the ulnar artery and superficial arch.

- Palmar arches are exposed via zigzag incisions extending proximally from the phalanges or through an inverted J-shaped incision in the palm. The ulnar artery is exposed using a zigzag incision more proximally in the palm. The wrist crease is crossed in an oblique fashion.

TECHNIQUES

■ Approach

- An incision is made that parallels the thenar crease, zigzags in the palm, and extends proximally into the forearm between the flexor carpi ulnaris and palmaris longus (**TECH FIG 1**).
 - Alternatively, two separate incisions can be made and the graft is tunneled under the skin, depending on the location of ulnar artery to be resected.
- The ulnar artery and nerve are identified 3 to 5 cm proximal to the wrist crease, and vessel loops are placed around each structure.
 - The artery is radial to the nerve at the wrist. The ulnar artery enters the hand through the Guyon canal. It runs deep to the volar carpal ligament and superficial to the transverse carpal ligament.

TECH FIG 1 • Planned incision to access the ulnar artery and superficial palmar arch. The wrist crease is crossed with an oblique incision. A zigzag incision is

made in the palm. If the entire superficial arch needs to be accessed, continue the incision along the proximal palmar crease. The extent of the forearm incision depends on the length of bypass required.

■ Dissection of the Ulnar Artery

- Dissect from proximal to distal, following the ulnar artery. First identify the patent portion of the ulnar artery proximal to the wrist crease (**TECH FIG 2A**).
- Identify the arterial branch or branches that accompany the deep motor branch of the ulnar nerve. Identify the origin of the proper digital artery to the small finger and the origins of the common digital arteries from the superficial arch.
- Mobilize the ulnar artery and superficial arch (**TECH FIG 2B**). Spread the artery away from surrounding tissue and venae comitantes using scissors. Venae comitantes are cauterized with bipolar electrocautery.

TECH FIG 2 • A. The ulnar artery is exposed in the forearm. **B.** The superficial palmar arch is exposed in the hand.

■ Resection of Affected Segment of Ulnar Artery and Superficial Arch

- All abnormal segments are resected to normal vessel.
- Once all damaged vessels are resected, distal outflow can be assessed by transiently deflating the tourniquet and observing backflow (**TECH FIG 3**).
- Measure the size of the defect.

TECH FIG 3 • The thrombosed section of ulnar artery and superficial arch is resected back to normal artery. Measure the segment that is resected in preparation for vein harvest.

■ Harvesting of Vein Graft

- Select the appropriate donor graft depending on the length and diameter needed (see Table 1).

- A vein graft is harvested through a longitudinal incision under tourniquet.
- Adequate length is mobilized (harvest 10%–30% longer than estimated to perform the bypass).
- Draw an axial line down the length of the vein to be harvested while it is still in situ. This will help the surgeon prevent inadvertent twisting of the graft during the anastomosis.
- Occasionally, branches are desired for anastomosis. All other branches are ligated or coagulated with bipolar electrocautery.
- Harvest the graft (**TECH FIG 4**).
- Reverse the vein graft and prepare for anastomosis.
- The vein is distended with heparinized saline, and veins are dilated.

TECH FIG 4 • The vein graft is harvested and reversed. A saphenous vein graft is pictured here.

■ Microvascular Anastomoses

- The proximal anastomosis is done first. End-to-side or end-to-end anastomosis of the graft to the ulnar artery stump is performed (**TECH FIG 5A**).
- End-to-end or end-to-side anastomoses are performed to the superficial arch or the common digital arteries, as indicated by the amount of resected artery (**TECH FIG 5B**).
- Size discrepancy is managed by making a closing V in the vein graft, an opening V in the artery, a sleeve anastomosis, or a 30-degree oblique cut in the artery (**TECH FIG 5C**).
- If multiple anastomoses are required, end-to-end and end-to-side repairs can be performed serially.
- Intravenous heparin 2000 units is given prior to tourniquet release. Dextran 40 is started at 20 mL/h in the operating room and continued postoperatively.

TECH FIG 5 • A. The vein graft is anastomosed into place. **B.** A branched graft is used in order to perform an end-to-end anastomosis to one common digital artery and end-to-side anastomoses to the remaining common digital arteries. **C.** Several methods of addressing an oversized vein graft are shown.

■ Assessing Flow and Closure

- Vascular clamps are released (or the tourniquet is deflated if this has not been done previously) after all anastomoses have been completed.
- Compress the radial artery manually for a few minutes to maximize flow across the anastomoses.
- Any leaks are repaired.
- A Doppler probe is used to assess distal arterial flow.
- Hemostasis is achieved.
- The wrist incision and vein donor sites are closed using 4-0 nylon sutures.
- Splint is placed to immobilize the operative site, with care to avoid any pressure on the underlying anastomosis.

PEARLS AND PITFALLS

Preoperative planning	■ Adequate arterial inflow and distal runoff is essential.
Technique	■ Resecting to normal intima is critical to success. ■ Use an extensile incision. ■ Close over a drain if indicated.
Vein grafting	■ A vein graft with a larger diameter than the artery does not usually pose a problem, but a vein graft that is significantly smaller than the artery leads to higher rates of thrombosis. ■ Anastomoses must be performed in a tension-free manner. ■ Set the tension to prevent kinking. ■ Avoid rotation of the graft. ■ For the proximal anastomosis, end-to-end anastomosis is easier, but end-to-side anastomosis will help to maintain any remaining circulation to the hand from the ulnar artery.
Postoperative expectations	■ Cold sensitivity is expected. ■ Recurrent thrombosis is possible and has been reported up to 10 years postoperatively.

POSTOPERATIVE CARE

- The operative extremity is splinted from fingertips to elbow, with care to avoid pressure on the anastomosis.
- No nicotine, caffeine, or chocolate
- The patient's room is kept warm, or alternatively, we use a Bair Hugger over the operative extremity. The room should also remain quiet and free of unnecessary stimuli.
- Dextran 40 is continued at 20 mL/h for 2 to 5 days.
- The patient is given aspirin 81 mg daily for 3 months.
- Anxiolytics can be used to protect the patient from damaging the repair inadvertently.
- Sutures are removed at 10 to 14 days postoperative.
- The patient is kept off of work for at least 4 to 6 weeks, or potentially longer depending on the nature of his or her occupation.
- The patient is forever forbidden from using the hand as a hammer.

OUTCOMES

- Most patients have continued symptoms, but with decreased frequency and severity.
- In a series of 47 patients, Marie et al.⁶ found that digital necrosis healed, and there was no recurrence of hypothenar hammer syndrome after surgical intervention.
 - Recurrence of hypothenar hammer syndrome was 27.7% after medical management. Of the patients in this study, 69.2% continued to smoke.
- Long-term patency rates of arterial grafts are higher than venous grafts. Venous graft patency ranges from 77% to 88%.⁷
- Chloros et al.⁸ studied 13 patients who underwent reverse interpositional vein grafting for post-traumatic ulnar artery thrombosis with a minimum of 2-year follow-up.
 - Ten of 13 grafts (77%) were patent at final follow-up.
 - Patients with patent grafts all significantly improved on the Levine symptom scale, McGill visual analog pain scale, McCabe cold sensitivity severity scale, and isolated cold stress testing.
 - Patients with nonpatent grafts were more likely to complain of pain, numbness, and cold sensitivity.

COMPLICATIONS

- Persistent cold intolerance
- Thrombosis of the graft
- Donor site complications (neuroma)
- Wound healing complications
- Hand stiffness

56 Second Toe to Thumb Transfer

CHAPTER

John R. Lien and Kevin C. Chung

DEFINITION

- The thumb is critical for hand function.
- Toe to thumb transfer is a composite tissue microsurgical reconstructive option for patients with loss of significant thumb length.

ANATOMY

- Great toe
 - Wider pulp and nail plate than native thumb and lesser toes; “thumblike” appearance
 - Significant aesthetic and functional morbidity at donor site; difficulty with push-off during gait
- Second toe
 - Pulp is bulbous and more rectangular in appearance than the native thumb or fingers.
 - Interphalangeal joints tend to claw.
 - Superior cosmetic and functional results on donor foot
- Arterial anatomy of the foot
 - The anterior tibial artery becomes the dorsalis pedis artery (DPA) distal to the ankle extensor retinaculum. The DPA courses along the dorsal foot lateral to the extensor hallucis longus tendon.
 - At the first intermetatarsal space, the DPA terminally divides into the first dorsal metatarsal artery (FDMA) and the deep plantar artery. The deep plantar artery communicates with the deep plantar arch of the foot, connecting the dorsal and plantar arches (**FIG 1**).
 - The FDMA generally travels deep to the extensor hallucis brevis tendon and

usually dorsal to the first dorsal interosseous muscle. It then communicates (through the distal communicating artery) with the first plantar metatarsal artery (FPMA) distal to the deep intermetatarsal ligament. The FDMA also terminally branches into the lateral dorsal digital artery of the great toe and medial dorsal digital artery of the second toe, which are of small caliber and clinically insignificant¹ (see **FIG 1**).

- **FIG 2** shows variants of FDMA anatomy in relation to the first dorsal interosseous muscle, as well as a variant unfavorable for vascular anastomosis.
- The plantar digital arteries are the effective blood source to the great and second toes. Their origin is the distal communicating artery connecting the FDMA and FPDA distally (**FIG 3**).
- Venous anatomy of foot
 - The superficial dorsal venous system is utilized for venous anastomosis.
 - The dorsal veins of the toes join the dorsal venous arch in the forefoot, which supplies the greater and lesser saphenous veins.
- Sensory nerve anatomy of foot
 - The superficial peroneal nerve innervates the dorsal foot while the deep peroneal nerve innervates the first dorsal web space.
 - Branches from the posterior tibial nerve innervate the plantar foot and toe pulps. Coaptation of plantar digital nerves are important for pulp sensation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Advanced age is not a contraindication to surgery, but the patient must be in generally good health to tolerate a prolonged surgery.
- Active nicotine use and a history of atherosclerotic disease are contraindications to toe transfer.
- Assess whether there is adequate, supple skin coverage. If not, consider a staged procedure (groin flap) to increase pliable tissue at the recipient site. Harvesting too much soft tissue from the foot will lead to foot deformity and marked donor-site morbidity.

FIG 1 • Dorsal foot arterial anatomy: (1) dorsalis pedis artery (DPA), (2) deep plantar artery, (3) first plantar metatarsal artery (FPMA), (4) first dorsal metatarsal artery (FDMA), (5) dorsal digital arteries, (6) distal communicating branch (intersection of the FDMA and FPMA), (7) plantar digital arteries.

FIG 2 • Variants of first dorsal metatarsal artery (FDMA) anatomy. In type I, the FDMA passes superficial (IA) or within (IB) the interosseous muscle belly. In type II, the FDMA passes at the deep aspect of the interosseous muscle belly but superficial to the intermetatarsal ligament. Type IIA includes a fine accessory branch superficial to the interosseous muscle, whereas IIB does not have an accessory branch. In type III, the FDMA is miniscule or absent with plantar-dominant (FPMA) flow.

- The level of thumb amputation will dictate harvest length.
- Assess the donor foot (contralateral foot for second toe transfer) to ensure no

prior trauma or surgery that would alter vascular anatomy to the second toe. Doppler ultrasound examination can be used to confirm presence of DPA and FDMA.

IMAGING

- Review preoperative radiographs of the recipient site to prepare for bone fixation and length requirement of donor toe (**FIG 4**).
- We do not routinely obtain preoperative angiography of the foot, but this is an option if there is concern for altered vascular anatomy on physical and Doppler exam.

SURGICAL MANAGEMENT

- Toe to thumb transfer is generally performed after the acute traumatic injury has healed and adequate soft tissue coverage is obtained.
- Ensure adequate soft tissue coverage and pliability prior to transfer.
- Amputations through the thumb metacarpal (with preserved carpometacarpal joint) or proximal half of the proximal phalanx are good candidates for toe transfer. We prefer the second toe transfer to minimize donor-site morbidity. Other options for toe transfer include great toe and trimmed great toe. Alternatives to toe transfer include metacarpal bone lengthening and on-top plasty. Osteoplastic reconstruction of the thumb using iliac crest bone graft and groin flap is of historical significance only.

FIG 3 • First web space arterial anatomy.

FIG 4 • Preoperative radiograph of recipient hand. Amputation level is at the proximal phalanx base. Contralateral radiographs help estimate defect length.

- Amputations at the distal proximal phalanx or distal phalanx often retain enough length for thumb function. Web space deepening may be performed as needed.
- Amputations through the base of the metacarpal or through the carpometacarpal joint require index finger pollicization to recreate a basilar thumb joint.

Preoperative Planning

- The contralateral toe vascular pedicle is in a better position for radial artery anastomosis at the snuffbox.
- The length of the transferred toe should be based on the length of the contralateral uninjured thumb (see **FIG 4**).
- A two-team approach is preferable to minimize operative time. One team

prepares the recipient site while the other harvests the contralateral toe.

- Good communication between teams is necessary to harvest tendons, nerves, and vessels of adequate length and caliber for primary repair.

Positioning

- Supine
- General anesthesia
- Thigh and arm tourniquets
- The recipient upper extremity and contralateral donor lower extremity are prepped.

Approach

- For second toe transfer as well as great toe transfer, the FDMA is the preferred arterial supply.
- However, one may need to alter the approach and harvest the FPMA if it is dominant (about 20% of cases).

TECHNIQUES

■ Foot Exposure and Second Toe Harvest

- Identify and mark the DPA and FDMA using Doppler ultrasound probe.
- Identify the course of the dorsal forefoot veins to the greater saphenous vein on the dorsomedial foot.
- Design dorsal and plantar curvilinear incisions on the dorsal and plantar foot (**TECH FIG 1A,B**).
 - Avoid incision over the thick plantar skin overlying the weight-bearing first metatarsal head.
- Gravity exsanguinate the limb and inflate the tourniquet.
- Perform an incision over the first web space and identify the vascular pattern of the FDMA using retrograde dissection (**TECH FIG 1C**). Be sure to visualize the proper palmar digital artery to the second toe.
 - A dorsal-dominant system is present in most cases. In this case, continue proximal dissection along the FDMA and DPA after ligating the communicating branch to the proximal FPMA. If necessary, perform

intramuscular dissection through the first dorsal interosseous muscle. If planning an osteotomy of the second metacarpal shaft to restore length of significant metacarpal thumb defects, preserve the vascular connections between the FDMA and second metatarsal. This is performed by preserving the interposed interosseous muscle.

- If the patient has a plantar-dominant system, divide the deep intermetatarsal ligament and dissect the FPMA proximally. We often do dissect out the more inaccessible FPMA in case the dorsal circulation is insufficient to perfuse the toe, which may require anastomosis of the FPMA.
- Extend the dorsal incision proximally and identify the dorsal vein to the second toe, and extensor digitorum longus. The extensor digitorum brevis is divided (**TECH FIG 1D,E**).
- Perform the plantar curvilinear incision and identify the flexor digitorum profundus tendon and both plantar digital nerves (**TECH FIG 1F**).
- Perform the osteotomy at the planned level with a microsagittal saw while protecting identified structures.
- Alternatively, a metatarsophalangeal disarticulation is an option depending on length needs. Detach the collateral ligaments and volar plate from the metatarsal head.

A

B

C

D

E

F

G

H

TECH FIG 1 • A,B. Donor foot incisions. Dorsal and plantar curvilinear incisions avoid the weight-bearing plantar first metatarsal head. **C.** First web space dissection. Note the palmar digital arteries (PDA) and the distal communicating artery (DCA) to the FPMA. The forceps is overlying the FDMA. **D,E.** Dorsal exposure of second toe. **F.** Plantar foot dissection. Note the plantar digital nerves (PDN) and flexor digitorum longus (FDL). **G,H.** Completion of second toe harvest. In this case, a metatarsophalangeal disarticulation was performed. Note the metatarsal head (MT) in the wound. **I,J.** Donor foot closure. Note preservation of the longitudinal and transverse arches of the foot.

- Determine the proper length of appropriate structures in the toe. Divide the nerves and tendons, taking care to tag the nerves with fine suture (6-0 Prolene) for easy identification. Leave the vessels intact.
- Deflate the tourniquet and check perfusion of the toe. It may take 5 minutes of warming the toe before adequate perfusion is seen.
- Once adequate perfusion is appreciated and the recipient site is ready, detach the dorsalis pedis artery and dorsal vein (**TECH FIG 1G,H**).
- Use nonabsorbable suture to repair the deep intermetatarsal ligament if transected.
- Obtain hemostasis and then close the wound primarily (**TECH FIG 1I,J**).

■ Recipient Site Preparation

- Create an incision at the thumb amputation stump and extend it proximally with a dorsal zigzag incision toward the anatomical snuffbox (**TECH FIG 2A,B**).
 - If previous soft tissue transfer was performed, elevate the margin of the tissue flap dorsally.
- Identify the radial artery at the snuffbox, cephalic vein, and dorsal branch of superficial radial nerve (**TECH FIG 2C,D**).
- Identify the residual extensor pollicis longus (EPL) tendon and perform a tenolysis to ensure free gliding. If the EPL is not salvageable, transfer the extensor indicis proprius (EIP) tendon.
- Extend the incision on the palmar residual thumb to identify the digital nerves of the thumb and flexor pollicis longus (FPL) tendon. A counterincision may be necessary at the carpal tunnel to retrieve the FPL tendon.
- Debride the residual metacarpal or proximal phalangeal bone of any fibrous scar or articular remnants. Preserve thenar muscle attachments to the metacarpal.

TECH FIG 2 • A,B. Dorsal and palmar thumb incisions. The dorsal incision must extend proximally to the anatomical snuffbox to allow for arterial anastomosis to the radial artery. **C,D.** Recipient site preparation. FPL, flexor pollicis longus; EPL, extensor pollicis longus.

■ Transfer of Second Toe

- Kirschner wire, 90-90 intraosseous wiring, and rigid plate fixation are options for bone fixation.
 - We prefer two longitudinal Kirschner wires for ease of fixation and less soft tissue dissection inherent with plate fixation.
- However, using plate fixation does have the advantage of initiating more aggressive tendon gliding exercises.
- After bone fixation, the flexor digitorum profundus tendon of the toe is transferred to the FPL tendon using four- or six-core strand repair technique.
- The extensor digitorum longus is weaved to the EPL or EIP tendon using Pulvertaft technique. Tension this weave tightly.
- Using microsurgical technique, the radial and ulnar digital arteries are coapted as distally as possible to promote early sensory recovery.
- Repair any branches of the superficial radial nerve to the superficial and deep peroneal nerves dorsally.
- The arterial anastomosis is performed in an end-to-side fashion to the radial

artery at the snuffbox. The venous anastomosis is then performed to a dorsal hand vein, feeding into the cephalic vein.

- The transferred toe is warmed, and perfusion is assessed.
- The wounds are then closed loosely to avoid compression of the dorsal anastomoses (**TECH FIG 3**).

TECH FIG 3 • A,B. Thumb closure.

PEARLS AND PITFALLS

Preoperative evaluation

- Ensure adequate soft tissue coverage and pliability prior to transfer. Otherwise, wound closure will be difficult and cause potential compression of the vascular anastomosis.

FDMA dissection

- Retrograde dissection of the first web space facilitates efficient identification of the variations in FDMA anatomy. Identify the FDMA, the distal communicating artery to the FPMA, and the

	medial and lateral plantar digital arteries to the great and second toe, respectively.
FPMA dominant pedicle harvest	■ If there is only one sizeable vessel that is plantar to the deep intermetatarsal ligament, the toe pedicle should be harvested based on the FPMA through the plantar incision. The dissection is challenging proximal to the metatarsal neck, and for this reason, we avoid more proximal dissection and use an interpositional vein graft to augment our arterial pedicle length.
Claw deformity of the transferred toe	■ The lesser toes tend to form claw deformities at the interphalangeal joint. If this causes a functional problem for the patient in subsequent follow-up, consider interphalangeal joint arthrodesis.

POSTOPERATIVE CARE

- The hand is placed in a well-padded volar forearm-based thumb spica splint with dorsal window and elevated at heart level in a warm room.
- Transferred digit skin color, capillary refill, and Doppler ultrasound checks are performed hourly for the first 48 hours.
- Oral aspirin is administered daily for 2 weeks.
- Prophylactic heparin or low molecular weight heparin anticoagulation per inpatient hospital protocol is performed.
- Patient is kept non-weight bearing to the donor foot for two weeks until sutures are removed.
- At 4 to 6 weeks postoperatively, we remove the Kirschner wires and begin tendon motion protocol.

OUTCOMES

- Toe to hand transfer is a safe procedure, with approximately 95% success rate in experienced centers (**FIG 5**).

FIG 5 • Successful toe transfer at 6-year postoperative visit. **A.** Radiographs demonstrate preservation of metacarpophalangeal joint articulation. **B.** Donor site with mild hypertrophic scar but overall good aesthetic appearance. **C,D.** Clinical photographs of hand.

- Toe transfer patients have superior outcomes in overall hand function, activities of daily living, work performance, aesthetics, and satisfaction compared to patients with thumb MCP level amputations without reconstruction.²
- Average static two-point discrimination is approximately 8 mm at long-term follow-up.³
- Average digit mobility was 33 degrees of flexion with extensor lag of 34.5

degrees at long-term follow-up for second toe to long finger transfer.³

COMPLICATIONS

- Arterial vasospasm is a potential complication and may occur within the first three days postoperatively.
 - If spasm occurs, consider loosening the dorsal sutures, placing the hand in a more dependent position, and use a warming lamp or warming blanket.
 - Papaverine or lidocaine can be injected.
 - Regional nerve block with a continuous flow catheter can be attempted.
 - If there is no improvement, return to the operative room and explore the anastomosis for thrombosis or compressive hematoma.
- If there is development of significant vascular congestion, loosen dorsal sutures and any potentially compressive dressings.
 - Consider venous exploration if there is no clinical improvement.

Section XI: Dupuytren Disease

57

CHAPTER Dupuytren Contracture

John R. Lien and Kevin C. Chung

DEFINITION

- Dupuytren disease is a benign fibroproliferative disorder affecting the palmar and digital fascia of the hand.
- Dupuytren disease can result in progressive contracture of the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints.

ANATOMY

- The palmar fascia consists of thenar, hypothenar, and central palmar aponeuroses.
- The palmar aponeurosis (PA) is usually involved with Dupuytren disease.
 - It is triangular with a proximal apex confluent with the palmaris longus tendon.
- The PA is a three-dimensional structure consisting of longitudinal, transverse, and vertical fibers (**FIG 1A**).
 - Longitudinal fibers fan out as pretendinous bands that bifurcate and divide into three layers extending to the distal palm (**FIG 1B**).
 - The first layer inserts into the dermis of the distal palm.
 - The second layer continues toward the digit as the spiral band, which lies deep to the natatory ligament and neurovascular bundle at the level of the palmodigital crease.
 - The third, deepest layer passes vertically toward the flexor tendon sheath.
 - Transverse fibers form the natatory ligament in the distal palm and the superficial transverse palmar ligament more proximally.

- Vertical fibers form the septa of Legueu and Juvara, which lie deep to the palmar fascia (**FIG 1C**). These eight septa form seven fibro-osseous compartments separating the flexor tendons from the lumbricals and neurovascular bundles. Superficial vertical bands of Grapow insert into the dermis of the palmar skin.
- Digital fascia
 - Grayson ligament is palmar to the neurovascular bundle.
 - Cleland ligament is dorsal to the neurovascular bundle.
 - The lateral digital sheet receives contributions from the natatory ligament and spiral band (**FIG 2**).
- PIP joint
 - The proximal attachment of the volar plate tapers into separate radial and ulnar bands, termed the checkrein ligaments (**FIG 3**).
 - The accessory collateral ligament arises from the head of the proximal phalanx and inserts on the volar plate.
 - The accessory collateral ligaments become lax in flexion and taut in extension.

FIG 1 • A. Anatomy of the palmar aponeurosis. **B.** Sagittal anatomy of the palmar aponeurosis. **C.** Septa of Legueu and Juvara are formed from the vertical deep extensions of the palmar aponeurosis.

PATHOGENESIS

- Nodules are often the first sign of Dupuytren disease. They are found superficially in the palm or finger, adherent to the dermis and underlying fascia.
- Normal fascial bands become pathologic cords.
- The pretendinous cord develops from the pretendinous band.
 - Cords are pathologic structures, whereas bands are normal structures.
 - Isolated pretendinous cords can result in MCP joint contracture.
- The spiral cord is composed of pathologic pretendinous band, spiral band,

lateral digital sheet, and Grayson ligament.

- The spiral course of this cord around the neurovascular bundle causes proximal, superficial, and central displacement of the bundle as it contracts (**FIG 4**).
- Spiral cords can cause MCP and PIP joint contracture.

FIG 2 • Digital fascia. Note the contributions of the natatory ligament and spiral band to the lateral digital sheet.

FIG 3 • Lateral (**A**) and volar (**B**) representations of the soft tissue support at the PIP joint. *Arrows* indicate the radial and ulnar checkrein ligaments. A, accessory collateral ligament; P, proper collateral ligament; VP, volar plate.

FIG 4 • In contrast to normal spiral cord anatomy (*left*), pathologic spiral cord anatomy (*right*) can displace the neurovascular bundle.

- The natatory cord can cause web space contracture.
- The central cord is a distal extension of the pretendinous cord in the palm but does not cause neurovascular bundle displacement.
- The lateral cord is diseased lateral digital sheet and can cause PIP joint contracture.
- The abductor digiti minimi cord runs from the abductor digiti minimi fascia to the base of the middle phalanx and can displace the neurovascular bundle toward the midline.
- The retrovascular cord causes flexion contracture of the distal interphalangeal joint.

NATURAL HISTORY

- Early presentation of Dupuytren disease causes isolated nodules and skin pitting.
- With progression of disease, pathologic cords will form.
- As cords contract, the MCP and PIP joints may be drawn into flexion.
- Fixed PIP joint contractures may develop over time.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with Dupuytren disease are commonly older men with northern European ancestry but can present in all ethnic groups and both genders.
- Dupuytren diathesis describes a predisposition toward aggressive disease and increased recurrence after surgical treatment. Five factors¹:
 - Male gender
 - Age of onset younger than 50 years
 - Family history with one or more affected siblings/parents
 - Ectopic lesions in the dorsal hand (Garrod pads)
 - Bilateral disease
- Palpate for thick, diffuse disease in the palm and finger, compared to discrete well-defined cords.
- Document the degree of MCP and PIP joint contracture.
 - If the cord spans the MCP and PIP joints, assess for fixed PIP contracture by testing passive PIP extension with the MP joint in maximal flexion.
- Examine for web space contracture.
- Carefully document the sensory examination, particularly if the patient has had previous surgery.

IMAGING

- Radiographs are obtained if there is a significant PIP joint flexion contracture.
 - Assess for articular congruency or arthritic change.

NONOPERATIVE MANAGEMENT

- Observation is appropriate for mild disease without compromise of function and minimal contracture.
- Percutaneous needle aponeurotomy (PNA) is mechanical division of a Dupuytren cord with the bevel of a hypodermic needle.
- Collagenase *Clostridium histolyticum* (CCH; Xiaflex, Auxilium

Pharmaceuticals, Inc., Malvern, PA) is an enzyme used for nonsurgical chemical division of Dupuytren cords. CCH therapy received Food and Drug Administration approval in 2010.²

- Consider CCH and PNA as a minimally invasive option for patients with discrete cords who meet indications for surgery. Patients may:
 - Wish to avoid the recovery associated with surgery
 - Have significant medical comorbidities precluding surgery
- We offer these minimally invasive options to patients with discrete palpable cords.

SURGICAL MANAGEMENT

- Limited fasciectomy excises diseased palmar and digital fascia. This is the most widely used surgical technique for Dupuytren contracture.
 - We prefer limited fasciectomy for patients with diffuse disease and severe PIP joint contractures or those who have failed PNA and/or CCH therapy.
- Indications for limited fasciectomy include the following:
 - Palpable disease with flexion contracture of the MCP joint greater than 30 degrees
 - Palpable disease with flexion contracture of the PIP joint greater than 15 degrees
- The “surgical techniques” discussed in this chapter include minimally invasive techniques discussed in nonoperative management (CCH and PNA).

Preoperative Planning

- Long-standing PIP joint contractures may persist after cord division or excision.
 - Consider PIP joint capsulotomy and checkrein release if residual contracture is present.
 - Review hand radiographs if the patient has significant contractures of the PIP joint. Consider arthrodesis in the setting of severe contracture or articular degeneration.

Positioning

- PNA
 - This procedure can be performed in an office procedure room or in the operating room.
 - Explain the procedure to the patient so that he/she will be prepared to

participate.

- Supine positioning with a hand table or padded Mayo stand.
- CCH
 - The patient is positioned sitting upright with the affected hand on the examination table.
 - Alternatively, position the patient supine with the hand on a Mayo stand.
- Limited fasciectomy
 - Upper arm tourniquet
 - Regional or general anesthesia
 - Supine positioning with a hand table

Approach

- PNA
 - The importance of reporting paresthesias or numbness to the fingertips is reviewed with the patient. Establish a baseline “normal sensation” to light touch of the radial and ulnar finger pulp.
 - Have the patient demonstrate short arc motion of the PIP and DIP joints; this will be useful to rule out intratendinous needle placement.
 - Cords are approached from distal to proximal for nerve monitoring.
 - Anesthetic is injected intradermally to avoid digital nerve anesthesia.
- CCH
 - Initial on-label use involved the injection of one cord at a time, and finger extension manipulation was recommended post injection day one. Recent studies broadened this approach.
 - Coleman et al.³ concluded that two affected joint contractures can be effectively and safely treated with concurrent injections. The incidence of multiple adverse events was higher, but the incidence of severe adverse events was not greater than single cord injection.
 - Compared to 1-day postinjection manipulation, 7-day postinjection manipulation had no significant differences in correction, pain, or skin tears.⁴ This suggests manipulation can be scheduled within the first 7 days after injection.
- Limited fasciectomy
 - Surgical incisions are variable and depend on the location of the cord (**FIG 5**).
 - Hand: For extensive palmar disease, make a transverse incision at the distal

palmar crease.

FIG 5 • Skin incisions for palmar fasciectomy.

- If there is significant MCP contracture, the distal palmar crease is left open to heal by secondary intention.
- Consider PIP joint volar capsulotomy if there is residual joint contracture after fasciectomy.

TECHNIQUES

■ Percutaneous Needle Aponeurotomy

- Prepare the hand with antiseptic solution.
- Plan and mark fasciotomy portals in areas with supple skin overlying a discrete linear cord (**TECH FIG 1A**). The cord should change from soft to

firm with joint extension.

- Portals are placed directly over the cord or along each side of the cord if it is broad.
- Space portals out at least 5 mm.
- Avoid portals over nodules.
- Avoid portals in skin creases because of:
 - Risk of skin tears
 - Proximity to flexor tendons
- Use a small probe to evaluate portals near skin dimples. To avoid entering a pit, avoid making the portal too close to the dimple sinus.
- Use a 30-gauge needle and inject 0.05 to 0.10 mL of anesthetic at the most distal portal site (**TECH FIG 1B**).
 - Penetrate into the dermis and then inject as the needle is withdrawn.
 - Do not inject subcutaneously.
- Place a 5/8-in. 25-gauge needle into the portal, with the needle bevel perpendicular to the cord fibers (**TECH FIG 1C**).
 - Nerve assessment: Ask the patient if he or she feels pain, paresthesia, or electric shocks along the finger. Reassess sensation to light touch along the side of the digit.
 - Tendon assessment: Have the patient slightly flex and extend the PIP and DIP joints. The needle should be withdrawn more superficial if there is needle bowing with flexor tendon excursion.
 - Repeatedly check nerve and tendon proximity to ensure the safety of the current portal.⁵
 - If the fingertip is numb, remove needle from current portal and move to a proximal portal.
 - If it is not, and the finger AROM does not catch the needle, continue with the current portal.
 - However, if the fingertip is not numb and the finger AROM *does* catch the needle, remove needle from current portal and move to a proximal portal.
- Hold tension on the cord by pulling adjacent skin or nodules.
 - Tension allows the needle to cut and moves the cord away from underlying structures.
- The cutting edge of the needle is used as a scalpel to divide the cord fibers deep to the dermis. Three maneuvers are performed (**TECH FIG 1D**)⁵:

- Clear: Use a side-to-side motion to clear a plane between the dermis and cord.
- Perforate.
 - Orient the needle vertically with the bevel transverse, and perforate the needle through the cord.
 - Pull the needle back superficial to the cord but still deep to dermis.
 - Using this up-and-down motion, move the needle radially and ulnarly to make multiple perforations at the level of the portal along the width of the cord.
 - Tactile feedback is important during this procedure, as one should feel a crackly or grating sensation as the bevel cuts the fascia.

TECH FIG 1 • Percutaneous needle aponeurotomy. **A.** Cords and portals. **B.** Start distally with portal anesthetic injection. **C.** Insertion of 25-gauge needle with bevel perpendicular to cord. Left thumb is used to hold tension on the cord without extending the digit. **D.** Needle maneuvers. **E.** Ring finger manipulation to rupture cord.

■ Sweep

- Once the cord is defined and perforated, use the needle bevel to

- transversely sweep across the width of the cord, from superficial to deep.
- Tactile feedback should include a scraping sensation with the needle.
 - Avoid being overaggressive to avoid neurovascular or tendon injury deep to the cord.
 - Rupture can be achieved without complete needle transection of the cord.
- If the patient reports shooting or electric pain along the finger at any time, reposition the needle to avoid nerve injury.
 - Move from distal to proximal portals and repeat the anesthetic injection and needle process.
 - Passively stretch after each portal release to attempt to rupture the cord (**TECH FIG 1D**).
 - If a portal looks concerning for skin tear, avoid manipulation until more proximal portals are established.
 - When the cord ruptures, an audible “pop” may be heard.
 - Reassess for residual flexion contracture.
 - If there is still palpable cord proximally, reassess for more portal placement and further fasciotomy.
 - Remember to monitor the nerve and tendon.
 - Once the procedure is complete, apply a Band-Aid on the portal sites. If a skin tear occurs, apply a soft bandage.
-

■ Collagenase Therapy⁶

- Before use, allow the vial containing the powder form of collagenase and the vial containing the diluent for reconstitution to stand at room temperature for 15 to 60 minutes. Remove the flip-off caps and clean the surface of the vials with alcohol (**TECH FIG 2A**).
- Using a 1-mL syringe with a 27-gauge 0.5-in. needle, withdraw the appropriate volume of diluent from the diluent vial (see package insert):
 - 0.39 mL for cords affecting the MCP joint
 - 0.31 mL for cords affecting the PIP joint
- Inject the diluent slowly into the sides of the vial containing the powder form of Xiaflex.
- Slowly swirl the vial to ensure the powder is in solution. The reconstituted solution should be clear.

- Using a new 1-mL syringe with a 27-gauge 0.5-in. needle, withdraw the appropriate volume of reconstituted solution (containing 0.58 mg of Xiaflex):
 - 0.25 mL for cords affecting the MCP joint
 - 0.20 mL for cords affecting the PIP joint
- Do not inject local anesthetic as the tumescence may interfere with proper placement of the Xiaflex injection.
- Confirm the cord to be injected. The ideal site should be where the cord is maximally separated from the underlying flexor tendon and where the skin is not intimately adhered to the cord (**TECH FIG 2B**).
- Clean the injection site with an antiseptic.
- With the nondominant hand, secure the patient's hand and apply tension to the cord.
- With the dominant hand, place the needle into the cord, taking care to keep the needle within the cord.
 - If there is concern that the needle is in the flexor tendon, passively move the distal interphalangeal joint to assess for tension on the needle.
 - Reposition the needle as necessary.
- Once you are satisfied with needle placement, inject one-third of the dose into the cord (**TECH FIG 2C**).
- Next, withdraw the needle and reposition it slightly more distally in the cord (2–3 mm) and inject another one-third of the dose.
- Finally, withdraw the needle and position it in the cord proximal to the initial site of injection (2–3 mm) and inject the remaining dose into the cord.
- When administering two concurrent injections, use separate vials and syringes for each cord.
 - For multiple digit injections, begin with the more ulnar digit.
 - For multiple cords in one digit, begin injections in the proximal cord and move to the more distal cord (move from the MCP joint to the PIP joint).
- Place the treated hand in a soft bulky dressing.
- Patient should follow up 1 to 7 days post injection.
- Assess the cord for autorupture.
- Assess the involved joint range of motion.
- Apply local anesthetic to the area of manipulation.
- For MCP joint cords, apply extension force to the MCP joint while the wrist is held in a flexed position.

- For PIP joint cords, perform the finger extension maneuver with the MCP joint in a flexed position.
- Hold moderate extension pressure for 10 to 20 seconds.
- If the cord is not disrupted, second and third manipulation attempts are performed at 5- to 10-minute intervals.
- If the cord does not disrupt after three attempts, additional collagenase injections and manipulation are performed after 4 weeks.

TECH FIG 2 • Collagenase therapy. **A.** Powder, diluent, and needles for reconstitution and injection. **B.** Palpation of a pretendinous ring finger cord. **C.** Collagenase injection. Note multiple sites of injection along the cord.

■ Limited Fasciectomy

- If there is widespread disease in the palm, make a transverse incision in the distal palmar crease to allow access (see **FIG 5**).
- Make an oblique longitudinal incision proximally toward the apex of the

palmar aponeurosis.

- Make an incision from the distal palmar crease to the palmodigital crease.
 - This incision can be extended distally in the digit if there is digital involvement.
- If there is digital extension of disease, we prefer to extend the incision using modified Bruner incisions or a longitudinal midline incision with V-shaped extension (**TECH FIG 3A,B**).
- Raise skin flaps off the diseased fascia, taking care not to buttonhole through the dermis.
- Identify the neurovascular bundles proximally.
- Release the pretendinous cord proximally (**TECH FIG 3C**).
 - The MCP joint should extend, allowing better access and visualization distally.
- In the digit, raise full-thickness skin flaps and identify the neurovascular bundle proximally.
- Carefully dissect the neurovascular bundle from the cord from proximal to distal.
 - If the pretendinous cord extends into a spiral cord, the neurovascular bundle will be displaced proximal, toward the midline of the ray, and superficial. The cord will spiral deep and from central to lateral to the neurovascular bundle as it extends into the lateral digital sheet (**TECH FIG 3C**; see **FIG 4**).
- Once the neurovascular structures are identified and protected along the involved cord (**TECH FIG 3D**), separate and excise the diseased cord from the surrounding tissue.
- Reassess for residual joint contracture.
 - If there is a persistent PIP joint contracture after fasciectomy, consider volar capsulotomy.
- After fasciectomy and any other concurrent procedures, release the tourniquet.
 - Hemostasis is critical to prevent hematoma formation.
- If a longitudinal incision is made, make a Z-plasty at the flexion creases to prevent scar contracture (**TECH FIG 3E**).

TECH FIG 3 • Limited fasciectomy. Preferred digital incisions: modified Bruner incision **(A)** and longitudinal incision with V-Y advancement distally **(B)**. **C**. Release of pretendinous cord proximally. Note course of ulnar spiral cord (*blue*, dorsal to nerve) and digital nerve (*yellow*, superficial). **D**. After excision of spiral cord. **E**. Closure of incision after Z-plasty across flexion creases.

■ Close the skin loosely.

- Leave the transverse palm incision open to heal with secondary intention if there is significant tension with MCP joint extension.
 - The open palm technique will also decrease the risk of hematoma formation.
 - Apply a volar forearm-based extension splint.
 - If digital perfusion is compromised in full extension, allow the digit to remain slightly flexed. This can occur after correction of severe contractures.
-

■ PIP Joint Volar Capsulotomy

- If there is persistent PIP joint flexion contracture after fasciectomy, consider volar plate release.
- Identify and release the A3 pulley.
- Retract the flexor tendons with a Ragnell retractor.
- Identify the proximal volar plate, and release the checkrein ligaments (**TECH FIG 4**).
- If necessary, release the accessory collateral ligaments, which course from the condyle to the lateral edge of the volar plate.
- Gentle passive extension of the PIP joint should be achieved after sufficient release.
 - Reassess the vascularity of the digit with the joint fully extended. Splint in as much flexion as necessary to preserve perfusion to the digit.

TECH FIG 4 • Checkrein ligament release.

PEARLS AND PITFALLS

Indications

- Consider PNA or CCH in patients with discrete cords who will accept a higher recurrence rate in order to avoid surgery.
- Diffuse, matted disease without a defined cord is better suited for surgical fasciectomy.

PNA portal placement

- Avoid portals over flexion creases, nodules, and matted skin.

PNA nerve monitoring

- Use anesthetic sparingly to avoid nerve blockade. A sensate nerve with a cooperative patient will help avoid digital nerve injury.

PNA technique

- Do not pull on the fingertips to gain tension on the cord. This will place the flexor tendons under tension, increasing risk of

	tendon injury during needling. ■ Replace needles regularly, as a dull bevel impairs tactile feedback and will not cut cord fibers.
CCH injection technique	■ Avoid injection into the flexor tendon; injection should be superficial within the involved cord. ■ Slight resistance to injection is normal.
PNA and CCH finger extension technique	■ Isolate and extend each involved joint individually to minimize risk of skin tears. ■ Hold other joints in a flexed position to minimize skin tension.
Limited fasciectomy	■ Neurovascular bundles can be displaced to the midline by spiral cords. ■ Take care to dissect the nerve from proximal to distal prior to excision of diseased tissue. ■ Meticulous hemostasis and loose wound closure (or open palm technique) minimizes hematoma formation. ■ Hematoma formation can cause painful swelling and skin flap ischemia.

FIG 6 • A–C. Two-week postoperative visit after

percutaneous needle aponeurotomy of ring and small fingers, showing full active range of motion.

POSTOPERATIVE CARE

- PNA and CCH
 - Immediate active digital flexion and extension is encouraged (**FIG 6**).
 - No formal therapy is prescribed.
 - Skin tears are managed with local wound care.
 - Patients perform activities as tolerated.
- Limited fasciectomy
 - Remove the splint one week postoperatively.
 - Begin range of motion exercises.
 - For open palm wounds, local wound care with nonadherent gauze is initiated after splint removal.
 - For contractures involving the PIP joint, night extension splints are worn for 6 months postoperatively.

OUTCOMES

- PNA has a high rate of immediate contracture correction (less than 5-degree residual contracture).⁷
 - 98% success of MCP joint correction
 - 67% success of PIP joint correction
- PNA contracture recurrence rate is higher and occurs sooner compared to open fasciectomy.⁸
- With CCH, the overall rate of clinical success (residual contracture 0–5 degrees) ranges from 44% to 64%.^{2,9,10}
 - Higher success is reported for treatment of MCP contractures (65%–77%) compared to PIP contractures (28%–40%).
- CCH disease recurrence (20 degree or greater increase of joint contracture in the presence of a palpable cord) after 5 years is reported at 39% for MCP joints and 66% for PIP joints.¹¹
 - 16% of recurrent contractures underwent additional procedures, most commonly fasciectomy or repeated CCH therapy.
- 94% of MCP and 47% of PIP joints achieved clinical success with limited fasciectomy, with deformity correction to within 0 to 5 degrees of full extension.⁸

- 6 months postoperatively after limited fasciectomy, 73% of patients are satisfied with their hand function.¹²
- Volar capsulotomy is controversial, as combined volar capsulotomy and fasciectomy does not have better results than fasciectomy alone.¹³
- Recurrence rates vary due to inconsistent definitions, but a recent study demonstrates a 20.9% recurrence rate (defined as worsening of total passive extension deficit of 30 degrees or more in a ray) at 5 years postoperatively after limited fasciectomy, which is significantly lower than recurrence after PNA (85%).⁸

COMPLICATIONS

- PNA: Overall complication rate is low.⁷
 - 3.4% skin tear
 - 1.2% transient neuropraxia
 - 0.1% nerve laceration
- CCH¹⁴:
 - Skin tear
 - Peripheral edema
 - Contusion
 - Drug ineffective
 - Injection-site hematoma
 - Lymphadenopathy
 - Pain in extremity
 - Blood blister
 - Injection-site pain
 - Tenderness
 - Localized rash/pruritus
 - Flexor pulley injury
 - Flexor tendon rupture can occur with injection into the flexor tendon; care must be taken when treating the small finger.
- Limited fasciectomy
 - Hematoma
 - Infection
 - Skin flap necrosis
 - Postoperative stiffness
 - Subjective paresthesias
 - Digital nerve injury

- Digital ischemia
- Tendon injury

Section XII: Spastic Conditions

58 Elbow Extension Procedures

CHAPTER

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- The impairment suffered by patients with spastic conditions can be quite debilitating, robbing them of their ability to perform basic activities of daily living and independence.
- Depending on the level of spinal cord injury, the deficits, and, in turn, the options for reconstruction, can vary. Spinal segments C5 through T1 innervate the upper extremity.
- The International Classification for Surgery of the Hand in Tetraplegia (ICT)¹ is a useful way to group tetraplegic patients based on functioning muscles with strength of grade 4 or higher to determine the potential donors for tendon transfer:
 - Group 1: Brachioradialis (BR)
 - Group 2: Extensor carpi radialis longus (ECRL)
 - Group 3: Extensor carpi radialis brevis (ECRB)
 - Group 4: Pronator teres (PT)
 - Group 5: Flexor carpi radialis (FCR)
 - Group 6: Extensor digitorum communis (EDC) and finger extensors
 - Group 7: Extensor pollicis longus (EPL) and thumb extensors
 - Group 8: Finger flexors
 - Group 9: All except intrinsic muscles
- With spinal cord injury at the C5/C6 level, patients will maintain shoulder

function through an innervated deltoid muscle and maintain elbow flexion through innervated biceps and brachialis muscles.

- The role of the shoulder and elbow is to move the hands in a functional “workspace.” The forearm and wrist then position the hand in preparation for specific tasks of daily living.
- In spinal cord injury, a spastic elbow flexion contracture may develop from spasticity of the elbow flexors and an absence of elbow extension. The patient becomes entirely dependent on the weight of the forearm for stability, limiting the effective “workspace.” The ability to extend the hand an additional 12 in. from the body will provide an additional 800% of workspace.²
- An elbow extension deficit severely interferes with performing activities of daily living and with wheelchair propulsion. Active elbow extension gives the patient the ability to transfer and to provide pressure relief, reducing the risk of developing ischial or sacral pressure ulcers.
- In cases of cerebral palsy, stroke, or traumatic injury, an elbow extension deficit may also result from a fixed elbow flexion contracture from biceps, brachialis, or brachioradialis muscle contracture.
- The first priority in patients with spasticity and/or tetraplegia is to improve elbow extension. The outcome of any other reconstruction for improvement of wrist or hand function will be entirely dependent on the patient having a usable workspace to perform new functions.

ANATOMY

- The deltoid originates from the scapula and inserts on the lateral shaft of the humerus.
 - The axillary nerve and the posterior circumflex humeral artery supply the deltoid posteriorly after passing through the quadrangular space (**FIG 1**).
 - The average fiber length is nearly twice that of the triceps muscle giving it a large amount of excursion and a good potential donor for transfer.
- The biceps originates from the coracoid process and the supraglenoid tubercle inserting on the radial tuberosity and the bicipital aponeurosis.
 - It is innervated by the musculocutaneous nerve that travels between the biceps and the brachialis.
 - The boundaries of the cubital fossa are the pronator teres medially and the brachioradialis laterally. The brachial artery and the median nerve are medial to the biceps brachii tendon. Lateral to it is the lateral cutaneous nerve of the forearm (**FIG 2**).

- The biceps muscle has a large physiologic cross-sectional area and long fibers empowering it to exert large amplitudes of force.
- Transfer requires the biceps tendon to curve around the humerus either laterally across the radial nerve or medially across the ulnar nerve.
- The triceps originates from the infraglenoid tubercle of the scapula and the posterior superior humerus.
 - It has three heads that converge to form the central tendon of the triceps inserting on the posterior olecranon (**FIG 3**).
 - The radial nerve passes through the triangular space and travels posterior to the lateral head of the triceps from a medial to lateral direction in the radial groove of the humerus.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Factors that influence functional ability must be considered during the examination:
 - Whether the injury is neurologically complete
 - Cognitive impairment from brain injury
 - Age of the patient
 - Concomitant upper extremity injuries
 - Presence of uncontrolled spasticity
 - Contractures limiting mobility
 - Patient depression

FIG 1 • A. Posterior view of the deltoid. It originates

from the scapula and inserts on the anterolateral humerus to abduct the arm. **B.** It is supplied by the axillary nerve and the posterior circumflex humeral artery emerging from the quadrangular space.

- Patients with motor levels of C5 or higher ($ICT \geq 1$) will have deltoid, biceps, and brachialis function.
- The exam should include an accurate assessment of the range of motion of the elbow, including the strength of the deltoid and biceps muscles. Supple joints and a Medical Research Council (MRC) grade of 4 or higher are a prerequisite for tendon transfer.
- To test the posterior deltoid, the examiner places one palm on the patient's posterior humerus with the patient's arm in 90 degrees of abduction and the elbow in flexion. The patient is asked to push as hard as possible against the examiner's palm while the examiner places the other hand against the posterior half of the deltoid assessing its tension and mass.

FIG 2 • Biceps anatomy. A. The brachioradialis and the pronator teres form the respective lateral and medial boundaries of the cubital fossa. Note the relationship of the biceps with the median nerve and brachial artery. **B.** Transfer of the biceps tendon can be done laterally

crossing the radial nerve or medially crossing the ulnar nerve. Medial transfer is more often performed, particularly if the patient does not have ulnar nerve function.

FIG 3 • Triceps anatomy. The triceps tendon is identified and used for the deltoid and biceps transfers.

- If the examiner can easily push the patient's arm out of this position, the posterior deltoid likely does not have sufficient strength for transfer.²
- The role of the biceps muscle is to flex the elbow and supinate the forearm. Therefore, prior to consideration of the biceps as a donor muscle, examination of the supinator and brachialis muscles are imperative to ensure adequate

postoperative flexion and supination.

- Forearm supination without resistance activates the supinator, which can be palpated along the proximal radius. Similarly, elbow flexion without resistance will activate the brachialis, and it is palpable along the anterior humerus.
- If the exam is equivocal, the biceps may be paralyzed with injection of local anesthetic around the musculocutaneous nerve, facilitating an independent evaluation of the supinator and brachialis.³
- The patient's overall psychosocial and mental state must be evaluated.
 - This includes consideration of the patient's social support network and personal motivation for improvement of function.
 - There will be a long period of postoperative rehabilitation, and without long-term cooperation from the patient and adequate assistance, a successful outcome is unlikely.

IMAGING

- Plain radiography can identify the presence of heterotopic ossification, a potential cause of joint contracture that must be ruled out or treated before any tendon lengthening or transfer.
- If, despite clinical examination, the examiner is still uncertain of whether a muscle is under volitional control, electromyography focusing on the muscle of interest can help identify spastic and flaccid muscles and determine phasic activity.

NONOPERATIVE MANAGEMENT

- Attempts to control the position of the elbow can be done with serial splinting or casting. Phenol motor blocks have been used to alleviate spasticity.
- Patients who are many years from their injury may be well adapted to their deficits. For example, some will learn to substitute the biceps to propel themselves in a wheelchair and do not wish any surgical intervention.
- It is important to thoroughly question each individual patient to determine what the postoperative goal is and whether surgery can realistically attain that goal.

SURGICAL MANAGEMENT

- The primary goal of surgical intervention in spasticity is to achieve, maintain, or maximize the patient's physical independence. Any treatment that can improve a level of function will have a dramatic effect on the patient's

independence.

- The goals of reconstructing elbow extension are to provide improvement in the following activities⁴:
 - Reaching for an object above shoulder level
 - Driving
 - Handwriting
 - Wheelchair propulsion
 - Pressure relief when seated
 - Using the hand while supine
- In patients with multiple levels of deficits, the reconstitution of active elbow extension should be performed first. It not only will stabilize the elbow and facilitate the transfer of other muscles in the future, such as the brachioradialis, but also gives the patient confidence in the rest of his or her treatment.⁵
- The following principles of tendon transfers apply in reconstruction of spastic conditions:
 - Supple joints with a functional arc of motion
 - Sufficient strength of donor muscle for its new function
 - Although an MRC ≥ 4 is recommended, a muscle will lose one grade of strength after transfer, and therefore, an MRC of 5 is preferable.
 - Comparable force of contraction and excursion between the donor muscle and the muscle to be replaced
 - Synergy—motions that are synchronized during functional activity (finger flexion with wrist extension)
 - Transfer should occur across a healthy bed of tissue with minimal inflammation or scarring
 - Stabilization of a joint whenever a transfer spans multiple joints
 - Straight line of pull for the transfer whenever possible
 - Minimal morbidity from loss of the donor muscle
- Elbow extension can be restored with a posterior deltoid or biceps transfer to the triceps. In cases of contracture as a result of spasticity, tendon lengthening is another treatment option.
- Deltoid to triceps transfer
 - The deltoid transfer uses the posterior half of the deltoid muscle. There is minimal to no functional loss of the donor muscle, as arm abduction is preserved postoperatively.
 - The deltoid and the triceps are synergistic muscles. Reaching for an object

overhead involves abduction of the arm (deltoid) and extension of the elbow (triceps).

- One significant disadvantage of the posterior deltoid muscle is that it does not have sufficient length to be directly inserted into the triceps tendon. Therefore, the gap must be bridged with a free tendon graft.
- The deltoid transfer is also prone to stretching, particularly at the proximal suture repair between the deltoid and the tendon graft. The tendon elongation most commonly occurs during the first 4 to 6 weeks after surgery but has been found to occur months after surgery. Tendon elongation will result in a loss of strength and excursion for elbow extension. Thus, a strict and rigorous postoperative rehabilitation program is essential to optimize results.⁶
- Absolute contraindications include a fixed elbow contracture or inadequate posterior deltoid strength on clinical examination.
- Biceps to triceps transfer
 - A biceps to triceps transfer can be considered in cases where there is less than grade 4 strength of the posterior deltoid but biceps with strength of 4 or greater.
 - Patients with elbow contracture less than 20 degrees may benefit from biceps transfer over a deltoid transfer, because biceps lengthening would likely be necessary to correct the elbow contracture.
 - Although there is a postoperative reduction in elbow flexion power of up to 47% after biceps transfer, patients report that the significant functional improvement with added elbow extension far outweighs the decrease in flexion strength.^{7,8} Again, it is important to confirm that the patient has active supinator and brachialis muscles to minimize the elbow flexion deficits after biceps transfer.
 - Advantages of the biceps transfer over the deltoid transfer include a shorter operation, ability to use a tourniquet for a portion of the operation, avoiding the need for a tendon interposition graft, and the need to heal only one tendon junction to permit earlier mobilization.
 - Biceps transfer is not without its disadvantages. The transfer requires routing the biceps tendon around the humerus resulting in a drop in power across the transfer.
 - Furthermore, the biceps and triceps are antagonist muscles. Normally, with triceps contraction and elbow extension, the biceps muscle relaxes. However, after biceps to triceps transfer, biceps contraction is necessary to activate elbow extension. The patient will require a longer period of rehabilitation to

train the biceps to function as an elbow extensor.

- Tendon lengthening procedures for contracture
 - Patients with volitional control of the elbow and hand and with more than 40 degrees of contracture are candidates. Additionally, those without volitional control and more than 100 degrees of contracture would also benefit for help with personal hygiene.
 - Patients recovering from strokes are typically older with weaker muscles, resulting in poor recovery of motor function regardless of the surgical procedure. Stroke patients with contractures will likely have some benefit in correction of the contracture, but less likely to have a significant improvement in function.
 - For biceps or brachialis lengthening procedures, a fractional lengthening can be performed for mild contractures, whereas a Z-lengthening (step cut) is indicated for more severe contractures.

Preoperative Planning

- A local nerve block is a useful preoperative tool differentiating muscle spasticity from muscle contracture. In the case of contractures, movement will not improve with neuromuscular blockade.
- The underlying cause of the spasticity will guide preoperative preparation.
 - Cerebral palsy
 - Voluntary hand use, sensibility, intelligence quotient, and presence of athetosis must be measured. An uncooperative patient with limited preoperative function is unlikely to have significant postoperative functional improvement.
 - The examiner must confirm the cause of contracture: joint contracture, muscle contracture, or muscle spasticity. Unlike muscle or joint contractures, muscle spasticity presents with full range of motion of the affected joint. The contractures should be treated with either therapy or surgery before a tendon transfer.
 - Older patients may have learned to compensate for their disability, and reconstruction in those cases must be considered carefully.
- Stroke
 - Patients often present with hemiplegia of the upper extremity and less spasticity than younger patients.
 - Surgery should be delayed until there is maximal neurologic recovery,

typically around 12 to 18 months.

■ Traumatic brain injury

- On average, patients are younger than stroke patients and will present with a greater degree of spasticity.
- Trauma patients may also have concomitant injuries, heterotopic ossification, deformities from other fractures, and possible quadriplegic involvement that can complicate postoperative functional improvement. Each patient must be considered individually.
- Similar to cerebral palsy, patient cognition and cooperation is variable and must be carefully assessed preoperatively to predict likelihood of patient cooperation and a successful postoperative outcome.

- If the patient has had a contracture treated preoperatively, it is important to repeat examination of the range of motion on the day of surgery to confirm there is no contracture recurrence.

Positioning

- The patient is placed in a lateral decubitus position for the deltoid to triceps transfer.
- Alternatively, the patient can be supine with a surgical “bump” placed beneath the torso to elevate the shoulder anteriorly.
- The supine position is appropriate for the biceps to triceps transfer and the biceps/brachialis lengthening.
- A high proximal tourniquet can be applied for the biceps and brachialis lengthening, as well as for a portion of the biceps to triceps transfer.

Approach

- A variety of tendon grafts can be used for the deltoid to triceps transfer, including toe extensors, tensor fascia lata, tibialis anterior, extensor carpi ulnaris, or the central third of the triceps tendon.
- The deltoid to triceps incision can be made as two separate incisions, one overlying the posterior deltoid and one over the triceps, or it can be made as one continuous incision.
- The biceps to triceps transfer can be performed by tunneling the biceps tendon either laterally or medially, though medially is the preferred method to avoid compression of the radial nerve.^{8,9}

TECHNIQUES

■ Posterior Deltoid to Triceps Transfer

- To reach the triceps, the posterior deltoid must be lengthened with a free tendon graft harvested from the surgeon's preferred donor site. A free tensor fascia lata graft has sufficient length and strength and leaves minimal donor-site morbidity (**TECH FIG 1A,B**).
- Make an S-shaped incision from the posterior tip of the acromion to the deltoid insertion on the humerus (**TECH FIG 1C**).
- Dissect along the posterior edge of the deltoid from proximal to distal. Identify the tendinous band marking the separation between the middle and posterior parts of the deltoid.
- Sharply dissect the posterior muscle fibers from their insertion on the humerus. This measures an area of approximately 1×6 cm (**TECH FIG 1D**). Include the periosteum and a small rectangular strip of fascia to include tissue with sufficient strength to hold suture for the tendon repair and to provide as much length as possible.
 - Take care to avoid dissection too far distal. The radial nerve emerges several centimeters distal to the deltoid insertion and can be injured with overzealous dissection.
- Completely separate the posterior deltoid muscle fibers from the remainder of the muscle, providing approximately 3 cm of excursion (**TECH FIG 1E**).
 - Avoid injury to the axillary nerve and the posterior circumflex pedicle, located approximately 10 cm proximal to the insertion on the humerus.
- To expose the triceps tendon and fascia, make a separate lazy-S incision along the distal third of the humerus lateral to the olecranon process (see **TECH FIG 1A,B**).
- Create a subcutaneous tunnel connecting the proximal and distal incisions (see **TECH FIG 1E**).
- First, interweave the graft proximally to the deltoid. Then, secure the tendon graft to the triceps tendon under moderate tension with the elbow fully extended and the shoulder slightly abducted. Secure the repair with two double rows of 4-0 nonabsorbable, running suture (**TECH FIG 1F**).
- Ensure adequate hemostasis and close the incisions primarily.

- Apply a splint with the elbow in 5 to 10 degrees of flexion.

TECH FIG 1 • A,B. The gap between the deltoid tendon and the triceps tendon must be bridged with a tendon graft. **C.** The deltoid is palpated and marked out with a dashed line. The incision is a lazy-S, spanning from the proximal extent of the muscle to near its insertion. The triceps incision is similarly S-shaped and is placed lateral to the lateral epicondyle to avoid potential pressure necrosis. **D.** The posterior deltoid is freed from its attachments to the humerus and will be transferred posteriorly toward the triceps tendon. **E.** The posterior deltoid (held by left clamp) after dissection has an approximate 3-cm excursion. The triceps tendon (held in right clamp) is prepared for

the transfer. The free tensor fascia lata graft has sufficient length and strength for transfer. **F.** Suture repair of the tendon graft to the deltoid proximally (*left*) and the triceps distally (*right*).

■ Biceps to Triceps Transfer

- Make an anterior longitudinal incision over the medial biceps muscle belly. Extend the incision obliquely across the antecubital fossa (**TECH FIG 2A**).
- Dissect and expose the biceps muscle. Identify and protect the musculocutaneous nerve.
- Divide the lacertus fibrosus while avoiding injury to the brachial artery and the median nerve lying deep to it. If the lacertus fibrosus has a substantial antebrachial fascia, preserve to use as an additional tail for subsequent tendon weaving (**TECH FIG 2B**).
- Identify the biceps tendon and trace it distally to its insertion on the radial tuberosity. To identify the radial tuberosity, flex the elbow and supinate the forearm.
- Detach the biceps tendon from its insertion as far distally as possible. Avoid injury to the recurrent radial vessels, as they are the main blood supply to the brachioradialis and the extensor carpi radialis, which may be donor muscles for potential future transfers.
- Place a braided, nonabsorbable suture through the substance of the biceps tendon.
- Make a second incision overlying the distal triceps aponeurosis. Ensure that the incision is lateral to the olecranon to avoid pressure ulceration and a narrow medial skin bridge.
- After exposing the triceps tendon, split it over the tip of the olecranon. Drill a unicortical hole into the medullary canal from the olecranon tip. This hole can be sequentially drilled to an appropriate size to receive the biceps tendon (**TECH FIG 2C**).
- From the posterior incision, create a generous subcutaneous tunnel medial to the humerus and deep to the ulnar nerve, traveling toward the anterior incision. The medial intermuscular septum may need to be resected to create the tunnel.

TECH FIG 2 • **A.** Anterior incision for exposure of the biceps. **B.** Elevation of the biceps tendon and the lacertus fibrosus. If the lacertus fibrosus is of substantial thickness, it can be preserved and used for the tendon weave. **C.** The biceps tendon is brought from the medial incision to the lateral incision through a subcutaneous tunnel. Sufficient proximal dissection of the biceps is necessary. **D.** The biceps tendon is brought through a slit in the triceps (posterior view). A unicortical hole is drilled in the proximal olecranon large enough to fit the biceps tendon. Two smaller distal holes are drilled in continuity with the proximal hole large enough to pass through a Keith needle with each end of the suture holding the biceps tendon. The

two ends of the suture are secured and tied over the olecranon.

- Free the biceps muscle as far proximally as possible to provide the straightest line of pull possible toward the olecranon. The tourniquet must be removed for this portion to permit adequate proximal exposure. Avoid injury to the vascular pedicle to the biceps, which enters the deep surface of the proximal third of the muscle. Proximal dissection should stop once the distal motor branches of the musculocutaneous nerve entering the biceps are identified.¹⁰
- Transfer the biceps tendon from the anterior incision medially toward the posterior incision (**TECH FIG 2D**).
- Pull the biceps tendon through the slit in the triceps tendon and secure with a Pulvertaft weave with a braided nonabsorbable suture. The tail of the biceps tendon should remain free to be brought through the olecranon.
- Drill two small holes through the opposite cortex of the olecranon to permit passage of a Keith needle. Secure a suture in the tail of the biceps and bring each end of the suture through each of the distal olecranon holes with a Keith needle. With the elbow in full extension, tie the two ends of the suture together over bone (**TECH FIG 2E**).⁹
- Place additional braided nonabsorbable sutures between the biceps and triceps tendon to further secure the transfer. If a tail of lacertus fibrosus was preserved, it can be secured at this time, either to the biceps tendon or to the triceps tendon.
- Set the tension maximally with the elbow held in full extension, such that the elbow cannot be passively flexed beyond 30 degrees when the arm is abducted about 30 to 40 degrees.⁸
- Achieve hemostasis, and close all skin incisions primarily. A suction drain can be placed at the surgeon's discretion.
- Place a splint holding the arm in 10 degrees of elbow flexion and the wrist in 30 degrees of extension. The shoulder is not immobilized.

■ Biceps and Brachialis Lengthening

- Make a 15-cm S-shaped incision across the antecubital fossa beginning laterally above the elbow and curving distally in an anteromedial direction

(**TECH FIG 3A**).

- Dissect from medial to lateral, exposing the lacertus fibrosus, biceps brachii tendon, median nerve, brachial artery, and the lateral antebrachial cutaneous nerve (see **FIG 2**).
- Identify the bicipital aponeurosis medial to the biceps brachii tendon, and resect it completely (**TECH FIG 3B**).
- Identify the lateral antebrachial cutaneous nerve between the biceps and brachialis lateral to the biceps tendon and retract it laterally. Expose the biceps completely and dissect distal to its insertion.
- For a fractional lengthening, make two cuts in a slightly oblique direction, spaced approximately 1 to 2 cm apart. One cut is made on the lateral side of the tendon, and the other is made on the medial side. The cuts should be no more than halfway through the tendinous portion of the musculotendinous junction, leaving the muscle fibers intact (**TECH FIG 3C**). Gently extend the elbow facilitating separation of the tenotomy sites, keeping the muscle in continuity.
- After release of the biceps, the brachialis can be visualized. Similarly, perform a fractional lengthening. Again, if two releasing incisions, space them approximately 1 to 2 cm apart and perform the proximal incision first. If the distal incision is made first, proximal migration of the brachialis will make it challenging to make the second incision (**TECH FIG 3D**).
- To perform a Z-lengthening of the biceps, make a transverse cut halfway through the tendon on the proximal side. Make a second distal transverse cut halfway through the opposite side of the tendon. The two cuts are connected longitudinally completely releasing the tendon with each end representing half the Z limbs (**TECH FIG 3E**).

TECH FIG 3 • **A.** Incision for biceps and brachialis lengthening. An S-shaped incision starts on the lateral arm and crosses the cubital fossa transversely to the medial forearm. **B.** Exposure of the bicipital

aponeurosis. **C.** Fractional lengthening of the biceps tendon. **D.** Fractional lengthening of the brachialis. **E.** Markings for Z-lengthening of the biceps tendon. **F.** Repair of the two ends of the biceps following Z-tenotomy and lengthening of the biceps.

- The elbow is extended to 30 degrees of flexion lengthening the tendon to the appropriate length. The two ends are sutured together where they remain overlapping using a Pulvertaft weave with 3-0 braided, nonabsorbable sutures (**TECH FIG 3F**).
- Be certain to perform the Z-lengthening over as much of the tendon length as possible to maximize the amount of tendon available for reattachment.
- If adequate lengthening of the brachialis cannot be obtained with fractional lengthening or Z-lengthening, the muscle can be completely transected.
- If preoperative evaluation revealed a spastic brachioradialis, it can be assessed for partial or complete release at this time. Dissect between the brachialis and brachioradialis to identify the origin of the brachioradialis. Perform the release (partial or complete) at the origin, permitting the muscle to slide distally. Be certain to identify and protect the radial nerve before performing a brachioradialis release.
- Release the tourniquet, achieve hemostasis, and close the wound primarily.
- Place the arm in a splint with the elbow at 30 degrees of flexion.

PEARLS AND PITFALLS

Incision

- Avoid making incisions directly over the olecranon to prevent pressure ulceration.
- Make a longitudinal incision on the lateral elbow for patients with contractures greater than 100 degrees facilitating skin closure with multiple Z-plasties if necessary.

Deltoid to triceps transfer

- A tendinous band in the intermediate part of the deltoid can be used to help demarcate the separation between the middle and posterior portions of the deltoid.
- Include the periosteum when dissecting the deltoid insertion from

	the humerus to better hold sutures for repair. ■ The axillary nerve is approximately 10 cm proximal to the humeral insertion of the deltoid and must be avoided.
Biceps to triceps transfer	■ Identify and protect the lateral cutaneous nerve of the forearm. ■ If using a tourniquet, release will be necessary to achieve adequate proximal dissection of the biceps. ■ Create a generous subcutaneous tunnel to avoid any compression or loss of strength of the transferred biceps tendon. ■ If the lacertus fibrosus has substantial fascia, it can be preserved and used as a second tail to further strengthen tendon weaving. ■ Medial routing of the biceps tendon avoids the potential for radial nerve palsy. ■ Avoid injury to the recurrent radial vessels so that the blood supply to potential donor muscles for future transfers is not compromised.
Biceps and brachialis lengthening	■ Perform a fractional lengthening in cases of mild contractures and a Z-lengthening for more severe contractures. ■ When performing a double incision release of the brachialis, perform the proximal incision first. ■ Avoid placing the elbow in full extension in patients with volitional control, as this may result in postoperative problems with elbow flexion.

POSTOPERATIVE CARE

- Deltoid and the biceps to triceps transfer
 - Immobilization is continued for 4 weeks. The patient is then placed in an active exercise program gradually increasing elbow flexion at a rate of 15 to 20 degrees per week with a daytime dial-hinge brace and a nighttime splint in full extension.
 - Occupational therapy is used to train biceps activation for elbow extension and to incorporate functional activities of daily living.⁸
 - The dial-hinge brace is continued until the patient is at 90 degrees of elbow flexion. The nighttime splint is used for 12 weeks, after which strengthening can begin.
- Biceps and brachialis lengthening
 - The wound is inspected and sutures removed in 10 to 14 days.
 - If a fractional lengthening was performed, the patient can begin mobilization immediately.

- For biceps Z-lengthening, the elbow is splinted in 30 degrees of flexion for 4 weeks to protect the tendon repair. Active and passive range of motion can then begin with nighttime splints worn for an additional 3 weeks for protection.

OUTCOMES

- The biceps comprises one of the two strong elbow flexors. Therefore, transfer does result in an approximate 47% reduction of preoperative strength.^{4,8}
- The biceps is an antagonist to the triceps, leading to a longer rehabilitation period to learn to activate it as an elbow extensor. This learning curve can vary from 2 to 6 months.^{4,8}
- Patients typically regain full or near full elbow extension against gravity with both tendon transfer techniques.^{2,3} In cases where patients do not, myofeedback with electrical stimulation can be used with good success.⁴
- On average, fractional lengthening of the biceps leads to a 10- to 30-degree improvement in flexion contracture with minimal loss of flexion power.
- For patients with a Z-lengthening procedure, there is on average a 45- to 60-degree improvement of elbow flexion contracture albeit with a loss of flexion power.

COMPLICATIONS

- Wound breakdown, infection, iatrogenic nerve injury, or inappropriate tensioning of a tendon transfer are all uncommon but possible surgical complications.
- For tendon transfers, tendon rupture or stretching of the repair can occur postoperatively leading to ineffective elbow extension. This can best be avoided with a strict postoperative immobilization and rehabilitation regimen.
- Tendon pullout from the olecranon is another potential complication that can best be prevented with a secure fixation.
- Though rare, compartment syndrome is a potential complication and can easily be missed in a patient with lack of preoperative sensation.³

CHAPTER Wrist Extension Procedures

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- Patients with tetraplegia may have difficulty with wrist extension, constantly assuming a partially flexed posture.
- A flexed wrist position diminishes the tenodesis effect on the digital flexors, leading to a weakened grip, difficulty with hygiene, and obstructed visual feedback when grabbing objects.
- After elbow extension, the second priority in reconstruction for tetraplegia or spinal cord injury is the restoration of wrist extension. Augmentation of wrist extension can indirectly enable passive thumb and finger flexion by improving pinch and grasp. This tenodesis effect is valuable in patients who do not have enough donor muscles to reconstruct active grasp and pinch.
- Those patients with an International Classification for Surgery of the Hand in Tetraplegia (ICT) score of 1 have an active brachioradialis that can be used for tendon transfer to augment wrist extension (see Table 1 from Elbow Extension chapter).

ANATOMY

- Tetraplegic patients with an active brachioradialis typically have an innervated biceps and brachialis muscle. Therefore, there is minimal donor-site morbidity on elbow flexion with its use for tendon transfer, making it a versatile workhorse muscle in tetraplegia reconstruction.
- The brachioradialis originates from the lateral supracondylar ridge of the humerus and the lateral intermuscular septum and inserts on the lateral base of the radial styloid beneath the tendons of the abductor pollicis longus and extensor pollicis brevis.

- It is innervated by a branch from the radial nerve entering the deep portion of the muscle, proximal to the elbow.
- The superficial branch of the radial nerve (radial sensory nerve) runs deep and medial to the brachioradialis between it and the supinator muscle. In the mid to distal forearm, the radial artery can be found between the brachioradialis and the flexor carpi radialis tendon (**FIG 1**).
- The brachioradialis is a long muscle with good excursion and a large circumference, giving it a high force of contraction.¹ Its tendon is bound with fascial coverings and does not glide freely past the mid-forearm (**FIG 2**).
- Releasing the tendon fascial attachments and freeing the muscle belly from the surrounding muscle significantly increases its excursion.²
- The extensor carpi radialis brevis (ECRB) attaches to the long finger metacarpal and is a more efficient wrist extensor than the extensor carpi radialis longus (ECRL), whose tendon attaches to the radial side of the second metacarpal, resulting in both extension and radial deviation of the wrist (**FIG 3**).

PATIENT HISTORY AND PHYSICAL FINDINGS

- As for all patients with spastic conditions considering surgical reconstruction, there are a variety of anatomic, functional, and psychosocial factors that must be examined (see Elbow Extension chapter).
- The strength of the brachioradialis must have a Medical Research Council grade 4 or higher. To test the brachioradialis, position the patient's elbow in a midprone position and have the patient flex against resistance contracting the brachioradialis. Palpate and attempt to move the belly of the muscle. If the muscle is tight, the brachioradialis has adequate strength for transfer (**FIG 4**).

FIG 1 • Relevant volar anatomy. Note the relationship of the brachioradialis with the sensory branch of the radial nerve and the radial artery.

- Examination also includes the wrist and metacarpophalangeal joints to ensure a full passive range of motion with good passive tenodesis of the fingers with wrist flexion and extension.³

IMAGING

- Electromyography can confirm volitional activity of the brachioradialis if the exam is equivocal. It will identify whether the muscle is spastic or flaccid and will determine its phasic activity.

FIG 2 • Excursion from dissection of the brachioradialis. **A.** A mark is placed on the distal tendon of the brachioradialis and extended to the surrounding tissue as a reference point. **B.** After ligation of the distal tendon and freeing the tendon and muscle attachments, there is approximately 3 cm of advancement beyond the reference point.

SURGICAL MANAGEMENT

- The goal of surgery is to improve pinch and grasp by taking advantage of the tenodesis effect. Wrist extension effectively lengthens the palmar surface of the wrist by increasing tension on the digital flexors and reducing tension on the digital extensors. This results in bringing the thumb and fingers into passive

flexion⁴ (**FIG 5**).

- With restoration or augmentation of active wrist extension, the patient can grasp light objects and pinch to hold and write with a pencil.
- Prerequisites include an active brachioradialis muscle and full range of motion of the wrist and MCP joints.
- The transfer can be performed with a number of other procedures as described by Moberg to maximize lateral pinch tenodesis⁵:
 - Resection of the thumb annular ligament to release the flexor pollicis longus (FPL) tendon over the metacarpophalangeal joint, increasing its mechanical advantage
 - Stabilization of the thumb interphalangeal joint with a buried Kirschner wire to prevent interphalangeal flexion with pinch (Froment sign)
 - Tenodesis of the FPL by attaching it to the volar radius
- It is best to delay tendon transfer for at least 1 year following injury to facilitate maximal recovery prior to surgical reconstruction.⁶

FIG 3 • Dorsal forearm anatomy. Note the location of

the extensor carpi radialis longus (ECRL) and the extensor carpi radialis brevis (ECRB).

FIG 4 • To examine the brachioradialis, place the patient's forearm in neutral position and ask the patient to flex the elbow against resistance. The prominence of the muscle belly is evident along the proximal radial forearm (*arrow*). Difficulty to displace the muscle with the examiner's hand confirms adequate strength for transfer.

FIG 5 • Active wrist extension results in finger flexion and automatic pinch via the tenodesis effect.

Preoperative Planning

- The patient's underlying cause of spasticity and the current psychosocial state must be carefully assessed before proceeding with surgical reconstruction (see Elbow Extension chapter).
- Any preoperative contractures must be diagnosed and treated with tendon transfer. A local nerve block can differentiate spasticity from contractures. Paralysis of the muscle will have no effect on contractures but will improve range of motion with spasticity.
- Contractures can be treated with occupational therapy, progressive splinting, or surgery depending on the severity.
- On the day of surgery, full range of motion must be confirmed before proceeding with a tendon transfer, particularly in patients who were treated for preoperative contractures.

Positioning

- The patient is positioned in the supine position with the arm extended on an armboard. A nonsterile upper arm tourniquet is applied to provide a bloodless operative field.

Approach

- The brachioradialis can be transferred to the ECRB or to both the ECRB and ECRL. Transfer to the ECRL alone is not advised, as this can lead to more radial deviation than wrist extension.^{3,6}

TECHNIQUES

■ Brachioradialis to Extensor Carpi Radialis Brevis Tendon Transfer

- Make a longitudinal dorsoradial incision from the midforearm to the wrist (**TECH FIG 1A**).
- Identify the brachioradialis, ECRL, and ECRB tendons (**TECH FIG 1B**).

- Longitudinally incise the paratenon of the brachioradialis. Sharply divide the terminal tendon as distal as possible under the abductor pollicis longus and the extensor pollicis brevis.
- Dissect along the deep aspect of the brachioradialis freeing it from its fascial connections proximally to the midforearm (**TECH FIG 1C**).
 - Take care to identify and protect the superficial branch of the radial nerve and the radial vessels during the dissection.
- Continue proximal dissection until an approximate 3 cm of excursion is obtained. If necessary, dissection can continue proximally to just distal to the elbow crease. The radial recurrent vessels traveling transversely on the deep aspect of the muscle mark the extent of the proximal dissection.
- Dissect the ECRB tendon proximally and sharply divide it at the level of the mid-forearm (**TECH FIG 1D**).
- Avoiding compression of the radial sensory nerve, transfer the brachioradialis dorsally toward the ECRB superficial to the ECRL.
- In an end-to-end fashion, perform a Pulvertaft weave between the brachioradialis and the ECRB using multiple 2-0 nonabsorbable braided sutures.
- Place the elbow in 90 degrees of flexion, the forearm in neutral, and the wrist in 45 degrees of extension prior to suturing the tendons.⁷ Do not pull up on the tendons when placing the first suture to avoid a lax repair once the tendon falls back to its natural position.
- Set the tension on the brachioradialis so that the normal resting length is re-established. To estimate this, passively stretch the muscle to its initial length relative to the radius. Place a mark on the brachioradialis tendon at its most proximal intersection with the ECRB tendon. Confirm that the mark remains in the same location after placement of all the sutures between the brachioradialis and ECRB.⁴
- The tension should be set such that the wrist is in a neutral to slightly extended position but passive flexion is still possible (**TECH FIG 1E**).
- Release the tourniquet, achieve hemostasis, and close the incision primarily.
- Place a splint holding the elbow in 90 degrees of flexion, the forearm in neutral rotation, and the wrist in 45 degrees of extension.

TECH FIG 1 • A. A longitudinal dorsoradial incision will provide exposure to the brachioradialis and the ECRB. The incision can be extended proximally, if necessary, for additional exposure of the brachioradialis. **B.** The brachioradialis, extensor carpi radialis longus, and extensor carpi radialis brevis in situ prior to dissection. **C.** After division of its distal tendon, dissection of the brachioradialis (*arrow*) proceeds proximally until there is approximately 3 cm of excursion. **D.** The ECRB is identified, and its tendon is incised proximally, permitting enough length for the transfer of the brachioradialis. **E.** The Pulvertaft weave completes the transfer. The weave is set with the elbow in 90

degrees of flexion, the forearm in neutral position, and the wrist in 45 degrees of extension. It is important to confirm that passive flexion of the wrist is possible at the completion of the transfer.

PEARLS AND PITFALLS

Tension

- Elbow extension causes a tenodesis effect on the brachioradialis. The tension should be set with the elbow flexed in 90 degrees to eliminate this effect.
- Postoperatively, the elbow should be immobilized in 90 degrees of flexion to minimize tension during tendon healing.

Neurovascular structures

- Identify and protect the radial sensory nerve before commencing dissection and before dividing the brachioradialis tendon.
- Do not injure the radial recurrent vessels when dissecting the BR proximally. They can be found on the deep surface of the muscle just distal to the elbow flexion crease signaling the extent of proximal dissection.
- The neurovascular supply to the brachioradialis should not be at risk because it enters the muscle proximal to the elbow.

Tendon transfer

- Free the brachioradialis until a 3-cm excursion is obtained.
- Tension on the brachioradialis should be set to re-establish normal resting length.

POSTOPERATIVE CARE

- After 4 weeks of immobilization, the patient can begin passive range of motion exercises with occupational therapy. The patient remains in a dorsal splint holding the wrist in 45 degrees of extension.
- Active range of motion exercises and strength training can begin 6 weeks after surgery. For 12 weeks, the patient remains in a protective splint removing it only to participate in therapy.

OUTCOMES

- The strength of wrist extension improves in almost all patients undergoing brachioradialis transfer without compromising strength in elbow flexion.^{3,6}
- The greater the preoperative strength of the brachioradialis and wrist extensors, the better the postoperative result.⁶

COMPLICATIONS

- Failures from tendon ruptures or adhesions are rare but can occur. Tenolysis should be delayed until 9 to 12 months after surgery.

60 Finger Extension Procedures

CHAPTER

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- Patients with spastic conditions may develop a finger flexion deformity resulting in difficulty with passive finger extension, even with the wrist in full flexion.
- The deformity can be quite severe with fingers clasped into the palm resulting in skin maceration and breakdown from the digging of fingernails into palmar skin.
- This also results in problems for the patient with activities of daily living and personal hygiene.

ANATOMY

- The flexor digitorum superficialis (FDS) and the flexor digitorum profundus (FDP) are most often involved in flexion deformities.
- The surgeon must be familiar with the volar forearm muscle anatomy, including the location of critical neurovascular structures such as the median nerve, ulnar nerve, radial artery, and ulnar artery.
- The FDS originates from the medial epicondyle, the coronoid process of the ulna, and the anterior oblique line of the radial head before splitting into four bellies at the junction between the middle and distal thirds of the radius. It has a humeroulnar head and a radial head, with the median nerve and ulnar artery traveling between them.
- Each muscle belly contributes a tendon that passes through the carpal tunnel and inserts on the middle phalanx of the corresponding digit (**FIG 1**).
- The tendons of the middle and ring finger travel volar to the tendons of the index and small finger through the carpal tunnel.

- The FDP originates from the proximal ulna and the interosseous membrane and sends tendons through the carpal tunnel to insert on the distal phalanges of the medial four digits.
- The extensor digitorum communis (EDC) origin is on the lateral epicondyle as a single muscle eventually splitting into separate muscle bellies to insert on the extensor expansions of the corresponding digits.

FIG 1 • Volar forearm anatomy. **A.** The flexor digitorum superficialis has a humeroulnar and a radial origin with insertion on the proximal phalanges of the medial four digits. **B.** The median nerve and ulnar artery travel between the two heads.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The exam must involve a full examination of all flexor muscles of the wrist, hand, and fingers.
- The patient typically presents with the fingers flexed into the palm. A thumb-in-palm deformity is also frequently present (**FIG 2**).

FIG 2 • Common clinical appearance of finger flexion deformity with flexed digits and a thumb in palm deformity.

- Any degree of active finger flexion or extension must be ascertained. The examiner can test active flexion by placing a finger in the patient's palm and asking the patient to grasp. Any increase in pressure indicates some degree of muscle control.
- Active extension can be tested by eliminating flexor tone with an anesthetic block of the median nerve in the antecubital space and the ulnar nerve in the cubital tunnel.
- Patients who have marked flexion of the proximal interphalangeal joints without flexion of the distal interphalangeal joints (DIP) likely have involvement of the FDS. On the other hand, flexion of the DIP suggests FDP involvement.
- To best differentiate between FDS and FDP involvement, examine the patient with the wrist flexed.
- It is imperative to examine the remainder of the hand for any other fixed contractures that could lead to a suboptimal postoperative outcome with a tendon transfer or fractional lengthening.

IMAGING

- Electromyography (EMG) may be helpful to evaluate which muscles are under volitional control prior to transfer.

SURGICAL MANAGEMENT

- Finger extension can be established with a tendon transfer or a fractional lengthening.
- The advantages of an FDS to EDC tendon transfer include a straight line of pull, sufficient power, and adequate excursion.¹
- Fractional lengthening is best performed for functional hands where the fingers cannot be actively extended with the wrist in a neutral position but can be extended when the wrist is flexed.
- The maximum length of excursion that can be gained from fractional lengthening is 2.5 cm. If a greater degree of lengthening is necessary, a transfer may be more appropriate.²

Preoperative Planning

- In cases of spasticity as a result of neurologic injury, it is important to delay surgery until there is a plateau in neurologic recovery, as the degree of spasticity can change with recovery.
 - This period of recovery can range from 6 to 18 months.
- For flexor lengthening, the amount of preoperative active extension is measured and noted, as this will be used to measure the amount of lengthening required intraoperatively.

Positioning

- Position the patient supine with the arm on an armboard. A nonsterile tourniquet can be applied to the upper arm to provide a relatively bloodless field during the procedure.

Approach

- The superficialis tendon can be routed through a radial or ulnar subcutaneous route or through the interosseous membrane.
- Either the superficialis tendon to the ring or the long finger can be used for transfer to the EDC.
- A longitudinal volar incision in the distal third of the forearm is typically used for fractional lengthening of the flexor tendons.

TECHNIQUES

■ Flexor Digitorum Superficialis to Extensor Digitorum Communis Tendon Transfer

- Make an approximate 5-cm longitudinal incision along the border of the volar mid-forearm (**TECH FIG 1A**).
 - Dissect through the subcutaneous tissue to visualize the pronator quadratus and the interosseous membrane.
- Make a transverse incision at the base of the long or ring finger. Carry out dissection through the palm and identify the interval in the flexor sheath between the A1 pulley and the A2 pulley.
 - While protecting the flexor digitorum profundus (FDP) tendon, sharply divide the flexor digitorum superficialis (FDS) proximal to Camper chiasm, which should be adequate length for transfer to the extensor digitorum communis (EDC).
 - Deliver the FDS through the forearm wound with the wrist flexed (**TECH FIG 1B**).
- Make a longitudinal incision along the dorsal hand to identify the EDC tendons (**TECH FIG 1C**).
- Create a radial-based subcutaneous tunnel from the volar incision to the dorsal incision. Avoid injury to the radial neurovascular structures. Transfer the FDS tendon through this tunnel from a volar to dorsal direction (**TECH FIG 1D**).
- Perform a Pulvertaft weave with the FDS tendon to the EDC tendons in an end-to-end fashion distal to the extensor retinaculum (**TECH FIG 1E**). Set the tension with the wrist in 30 degrees of extension while the assistant clenches the fingers and the thumb into a fist to ensure that the repair is not too tight. Range the wrist from 30 degrees flexion to 30 degrees of extension and observe the finger cascade to confirm an appropriate tenodesis effect. The fingers should passively extend with wrist flexion and passively flex with wrist extension. If this does not occur, the tension of the repair may need to be adjusted.
- Release the tourniquet and achieve hemostasis. Close all the wounds primarily.
- Apply a splint with the wrist and digits in extension to the level of the proximal interphalangeal joints.

TECH FIG 1 • **A.** Volar mid-forearm incision (*arrow*) to approach the flexor tendons both for the FDS to EDC transfer and for flexor lengthening. **B.** FDS tendon divided distally and delivered through proximal forearm wound. **C.** Dorsal incision with exposure of the extensor digitorum communis tendons. **D.** Transfer of the FDS tendon from a volar to dorsal direction around the radial side of the wrist. **E.** Pulvertaft weave of FDS to EDC in an end-to-end fashion.

■ Step-Cut Fractional Lengthening of Flexor Tendons

- Make an approximate 5-cm longitudinal volar incision in the mid-distal forearm overlying the musculotendinous junctions of the flexor muscles.
- Carry out subcutaneous dissection to visualize the tendinous portions of the flexor muscles (**TECH FIG 2A**).
- Identify the musculotendinous junction (**TECH FIG 2B**).
- Measure the amount of lengthening necessary by placing the wrist and digits in the position of maximum active extension determined preoperatively. From this position, passively extend the fingers and measure the amount of tendon excursion. The tendons will need to be lengthened by a value half of that measured.
- Obliquely divide each of the FDS tendons at the musculotendinous junction without injuring the muscle fibers (**TECH FIG 2C**). The vascularity and support of the muscle will be necessary for postoperative tendon healing.
- Passively extend each digit just short of the desired length and observe as the tendon and muscle fibers slide distally creating a 2- to 3-cm gap.
- If the procedure is also being performed for wrist flexion, first divide the flexor carpi radialis and flexor carpi ulnaris myotendinous junctions before the finger flexors.
- Determine if FDP lengthening is necessary by examining the amount of extension attained after FDS lengthening.
 - If FDP lengthening is required, dissect the FDP tendons.
 - During the dissection, carefully ligate small ulnar artery perforators with bipolar cautery to prevent postoperative bleeding.
 - Divide the FDP tendons at the musculotendinous junction as described above.
- The flexor pollicis longus tendon can also be lengthened if necessary.
- If, after dividing all the FDS and FDP tendons, there is still inadequate lengthening, a second recession can then be made.
- Deflate the tourniquet and achieve hemostasis. Close the incision primarily (**TECH FIG 2D**).
- Provided there is no excess tension on the neurovascular structures, splint the patient with the wrist in neutral position and permitting mobilization of the fingers.

TECH FIG 2 • **A.** Volar incision with visualization of the FDS tendon. **B.** The musculotendinous junction is identified and will be the location of the lengthening. **C.** Recessions made in the FDS and FDP. Note the lengthening of the tendon between the two forceps. **D.** Wound closure with the fingers in extension. Care is taken to appreciate any tension on neurovascular structures before closing the wound and splinting the fingers in extension.

PEARLS AND PITFALLS

Flexor digitorum superficialis to extensor digitorum communis transfer

- Confirm that the extensor retinaculum does not impinge on the conjoined tendons. It can be incised if necessary.
- Perform a Pulvertaft weave and confirm that appropriate tension has been set by observing the finger cascade with tenodesis of the wrist. Wrist extension should result in passive finger flexion. Similarly wrist flexion should result in passive finger extension.

Flexor lengthening

- Be certain to identify the median nerve prior to dividing any of the flexor tendons.

- Incise the flexor tendons within the muscle to provide adequate lengthening. Do not cut the tendons too distally.
- Do not incise the muscle belly when dividing the tendons.
- Re-examine the neurovascular structures prior to postoperative positioning to ensure there is no excess tension with the wrist in neutral position. If there is tension, position the wrist as close to neutral as possible.
- Do not fully extend the digits intraoperatively to prevent overcorrection and excess weakening of the flexor tendons, which can lead to a swan-neck deformity.

POSTOPERATIVE CARE

- After the FDS to EDC transfer, the postoperative splint is maintained for 4 weeks. At that point, the splint can be removed for therapy but is to otherwise be worn for another 2 weeks.
 - At 6 weeks, the patient will no longer need external support.
- After flexor tendon lengthening, active and active-assisted exercises begin on the first postoperative day. The immediate active motion permits the flexor tendons to continue to lengthen as necessary given each individual patient's tone and control.
- Passive extension can begin after 4 weeks, and the patient wears a custom orthotic to maintain passive extension for an additional month.
 - The patient can then transition to a nighttime orthotic for an additional 3 months.

OUTCOMES

- After the FDS to EDC transfer, almost all patients have an improvement in function with the majority being excellent to good.¹
- With flexor lengthening, improvement in function can be observed in up to 90% of patients.²

COMPLICATIONS

- With FDS to EDC transfer, patients may rarely develop postoperative extension contractures of the metacarpophalangeal joints necessitating a joint capsulectomy with extensor tenolysis.¹ Other possible complications include setting the tension too loosely or pulling out the tendon weave.
- Transfer of the FDS tendon can lead to proximal interphalangeal joint flexion contracture or hyperextension deformity. This can best be avoided by diving

the FDS tendon proximal to the decussation, and not at the level of its insertion, to prevent disruption of the blood supply to the profundus tendon.^{3,4}

- In flexor lengthening, it is possible to overlengthen the flexor tendons, leading to a loss of grip strength and a decrease in function.² Similarly, an inadequate lengthening can result in persistent postoperative flexion deformity.

61 Lateral Key Pinch Reconstruction

CHAPTER

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- Lateral key pinch is necessary to secure small objects for many activities of daily living including writing, feeding, drinking, and self-catheterization.
- The act of pinching involves four phases:
 - Object acquisition
 - Pinch/grasp
 - Holding/manipulation
 - Object release
- Patients with C5-C6 tetraplegia most often present with an International Classification for Surgery of the Hand in Tetraplegia (ICT) of 1 or higher. The only muscle available for transfer is the brachioradialis, which is typically used for wrist extension. Therefore, these patients are entirely dependent on tenodesis for passive lateral pinch, resulting in a weak pinch that often stretches with time.
- Patients with an ICT of 2 or more have active wrist extension and are candidates for augmentation of lateral pinch with a brachioradialis (BR) to flexor pollicis longus (FPL) transfer.
 - Those with ICT of 4 or higher are candidates for pronator teres (PT) transfer to the FPL, freeing up the BR for additional tendon transfers.

ANATOMY

- The surgeon must be familiar with the forearm anatomy, including the brachioradialis and its local neurovascular structures (**FIG 1**).
- Two-thirds of the pronator teres (PT) originates from the medial epicondyle inferior and lateral to the flexor carpi ulnaris. One-third originates from the

anterior proximal ulna. The PT has very little free tendon distal to its muscle belly, measuring approximately 1 cm and often blending with the periosteum.¹

- The FPL origin is the volar surface of the radius adjacent to the interosseous membrane, and it inserts on the base of the distal phalanx of the thumb. It runs in the same plane as the flexor digitorum profundus.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The exam should include a complete motor and sensory assessment of the extremity. Patients with inadequate sensation are less likely to use the reconstruction, leading to suboptimal outcomes.
- The patient's ability to perform baseline lateral pinch should be assessed, with the wrist in 30 degrees of flexion, neutral position, and 30 degrees of extension.
- The brachioradialis or the pronator teres must be confirmed to have a MRC grade 4 or higher prior to transfer.
- The strength of the brachioradialis must have a Medical Research Council grade 4 or higher. To test the brachioradialis, position the patient's elbow in a midprone position and have the patient flex against resistance contracting the brachioradialis. Palpate and attempt to move the belly of the muscle. If the muscle is tight, the brachioradialis has adequate strength for transfer (**FIG 2**).
- The pronator teres can be palpated on the lateral forearm distal to the antecubital fossa with resisted pronation.
- The index finger strength should be evaluated to ensure stability to serve as a post for the reconstructed thumb.

IMAGING

- If the examination is equivocal, electromyography (EMG) may be used to confirm or verify that the brachioradialis or pronator teres is under volitional control prior to transfer.

SURGICAL MANAGEMENT

- The goal of surgery is to establish a strong key pinch between the pulp of the thumb and the radial side of the index finger, independent of wrist extension.

FIG 1 • Relevant volar anatomy. Note the relationship of the brachioradialis with the sensory branch of the radial nerve and the radial artery.

FIG 2 • To examine the brachioradialis, place the patient's forearm in neutral position and ask the patient to flex the elbow against resistance. The prominence of the muscle belly is evident along the proximal radial forearm (*arrow*). Difficulty to displace the muscle with the examiner's hand confirms adequate strength for transfer.

- Prerequisites to surgery include² the following:
 - Stability in a wheelchair. The patient must be able to sit for extended periods of time to use the reconstruction for meaningful tasks.
 - Control of the elbow. Control of the arm and hand position in space is imperative for key pinch.
 - Ability to pronate the arm. With pronation, gravity will enable wrist flexion to releasing the pinch.
 - Sufficient power in wrist extension to augment the power of the pinch
 - Normal passive range of motion of the thumb carpometacarpal (CMC) joint
 - Stability of the index finger to serve as a post against which the thumb can push during pinch
- Patients should have intact two-point discrimination of less than 1.5 cm at the thumb and index finger.³
- Patients with active wrist extensors and the ability to passively or actively flex the fingers are the ideal candidates for active key pinch reconstruction.

- In patients with tetraplegia, activation of the FPL alone will often interfere with the normal balance of the thumb. This will lead to unpredictable thumb positioning and instability. To help circumvent this problem, the following procedures can accompany the tendon transfer to the FPL:
 - Preposition the thumb ray through a fusion at the CMC joint. This helps to stabilize the normally complex movements of the CMC saddle joint.
 - Stabilize the interphalangeal (IP) joint of the thumb to prevent IP joint hyperflexion from unopposed FPL flexion across the IP joint (Froment sign).
 - Tenodesis of the extensor pollicis longus (EPL) extending the IP joint of the thumb with wrist flexion to aid in release of the pinch
- In cases of spinal cord injury, it is important to delay the surgical intervention until the patient's recovery has plateaued, typically 12 to 18 months.

Preoperative Planning

- The patient's underlying cause of spasticity and the current psychosocial state must be carefully assessed before proceeding with surgical reconstruction (see chapter on Elbow Extension Procedures).
- Any contractures preventing passive range of motion must be treated prior to tendon transfer. On the day of surgery, the range of motion must be assessed to rule out recurrence of the contracture.

Positioning

- Position the patient supine with the arm extended on an armboard.
- An upper arm tourniquet can provide a relatively bloodless field during the procedure.

Approach

- The brachioradialis or the pronator teres can be utilized for transfer to the FPL depending on the number of active muscles available with an MRC score of 4 or higher.

TECHNIQUES

■ Brachioradialis/Pronator Teres to Flexor Pollicis

Longus Transfer

- Make an 8- to 10-cm longitudinal incision on the dorsoradial wrist beginning at the radial styloid and extending proximally.
- If the brachioradialis will be used for transfer, begin subcutaneous dissection and identify the tendon of the brachioradialis, the superficial branch of the radial nerve, and the radial artery. Protect the neurovascular structures, longitudinally incise the paratenon, and dissect the brachioradialis.
- Sharply divide the terminal tendon as distal as possible under the abductor pollicis longus and the extensor pollicis brevis.
- Dissect along the deep aspect of the muscle by freeing it from its fascial and muscle connections proximally toward the elbow. As dissection proceeds proximally from the tendon insertion, the radial artery and the dorsal sensory branch of the radial nerve become more prominent. Ligate the small perforating vessels entering the muscle belly.
- Continue proximal dissection until the radial recurrent vessels are identified. The vessels will be traveling transversely on the deep aspect of the muscle just distal to the elbow flexion crease.
 - This marks the extent of the proximal dissection.
- An approximate 3 cm of excursion will be obtained if the muscle is completely freed.
- If the pronator teres is to be used for transfer, identify and incise it at its insertion on the radius. Similar to the brachioradialis, elevate the PT from the radial periosteum proximally for 4 to 5 cm (**TECH FIG 1A**).
- Identify the FPL tendon deep to the flexor carpi radialis (FCR) and radial to the flexor digitorum profundus. Take care to identify and protect the radial artery. Divide the FPL 1 cm proximal to the proximal edge of the pronator quadratus (**TECH FIG 1B**).
- Tunnel the brachioradialis under the radial neurovascular bundle so that it can reach the FPL. Suture the BR or the PT tendon to the FPL with 2-0 nonabsorbable braided sutures with a Pulvertaft weave (**TECH FIG 1C**).
- Set the tension so that passive wrist flexion causes thumb abduction and extension and so that wrist extension flexes the thumb metacarpophalangeal joint, positioning the pulp of the thumb against the radial side of the middle phalanx of the index finger (**TECH FIG 1D,E**).
- Release the tourniquet and achieve hemostasis. Close the incisions primarily.

- Place a long-arm splint with the elbow in midprone position and 90 degrees of flexion, the wrist in 10 to 20 degrees of flexion, and the thumb in abduction.

TECH FIG 1 • A. Dissection of the pronator teres muscle. An approximate 4 to 5 cm of elevation off the periosteum of the radius is necessary. **B.** The FPL (*white arrow*) is identified and ligated proximal to the pronator quadratus for transfer. The *black arrow* indicates the brachioradialis. **C.** The brachioradialis (*black arrow*) is tunneled deep to the radial neurovascular bundle and sutured to the FPL with a Pulvertaft weave. **D,E.** The tension is set so that

passive wrist flexion causes thumb abduction and wrist extension positions the pulp of the thumb against the radial side of the middle phalanx of the index finger, effectively creating a pinch.

PEARLS AND PITFALLS

Patient selection

- Confirm that there is adequate index finger strength and stability to serve as a post for the thumb.
- Sensation is important for useful pinch function.

Surgical procedure

- Identify and protect the radial sensory nerve before dividing the brachioradialis tendon.
- Do not injure the radial recurrent vessels when dissecting the BR proximally. They can be found on the deep surface of the muscle just distal to the elbow flexion crease signaling the extent of proximal dissection.
- The neurovascular supply to the brachioradialis should not be at risk because it enters the muscle proximal to the elbow.
- Free the brachioradialis proximally to the level of the elbow (without injuring the vascular pedicle) to provide adequate excursion.
- Pass the brachioradialis deep (dorsal) to the radial artery before performing the tendon repair.
- Elevate the pronator teres off the radial periosteum for approximately 4–5 cm.
- Other procedures such as IP joint stabilization, CMC fusion, or EPL tenodesis may be necessary depending on the individual.

POSTOPERATIVE CARE

- The patient remains immobilized in a splint for 6 weeks followed by mobilization with occupational therapy.

OUTCOMES

- Patients can achieve an average postoperative key pinch strength of 2 kg, facilitating many activities of daily living including hygiene, grooming, mobility, and writing.³ The longevity of the reconstruction is excellent with a

minimal decrease in strength over time.⁴

COMPLICATIONS

- Tendon adhesions are a potential complication particularly if additional tendon transfers are being performed during the procedure.⁵
- Brachioradialis transfer to the FPL can result in hyperflexion of the interphalangeal joint resulting in a pinch posture between the dorsal distal thumb phalanx and the volar index middle phalanx.⁶ This can be addressed with stabilization of the IP joint.

62 Grasp Improvement Procedures

CHAPTER

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- The primary purpose of the hand is for gripping, feeling, and engaging in human contact. The capacity to pinch and grasp is key to productive gripping.
- With the ability to grasp objects in the palm, an individual can handle larger objects than would otherwise be possible with pinch alone. Manipulating cans, bottles, or a telephone becomes a reality, significantly expanding an individual's breadth and capacity to perform activities of daily living.
- Patients with a midlevel tetraplegia or International Classification for Surgery of the Hand in Tetraplegia (ICT) scores of 3 or higher have sufficient donor muscles for active grasp reconstruction (see chapter on Elbow Extension Procedures). The extensor carpi radialis longus (ECRL) can be used for tendon transfer while preserving the extensor carpi radialis brevis (ECRB) for active wrist extension.
- The ECRL is a good potential donor for active finger flexion because it is synergistic with the finger flexors. Normally, finger flexion is paired with wrist extension, making postoperative rehabilitation much easier for the patient.
- Additionally, patients with spasticity may present with fixed finger flexion deformities.
- A fixed flexion deformity of the flexor digitorum superficialis (FDS) and the flexor digitorum profundus (FDP) can lead to difficulty with personal skin care and hand hygiene.
 - An FDS to FDP (superficialis to profundus, STP) transfer can alleviate such contractures.
- Performing grasp is also challenging in patients with an intrinsic minus hand position: metacarpophalangeal (MCP) hyperextension and interphalangeal (IP)

flexion.

- A Zancolli lasso procedure using the FDS tendons can provide hand intrinsic balancing in patients with an intrinsic minus deformity via a dynamic tenodesis effect.

ANATOMY

- The surgeon must be familiar with the anatomy of the finger flexors including both the FDS and the FDP (see Finger Extension chapter).
- The ECRL originates from the distal supracondylar ridge and inserts on the base of the index metacarpal. It serves to extend and radially deviate the wrist.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The entire upper extremity must be examined for both motor and sensory function including range of motion. The evaluation must also incorporate the resting position of the hand, as this will guide the surgical approach. Patients with a contracture and flexion posture of the fingers will benefit from an STP transfer, whereas those with clawing may require a lasso procedure.
- In patients with tetraplegia, the ICT score must be determined. Both the ECRL and the ECRB must be active with sufficient wrist extension if the ECRL is to be used as a donor muscle for active grasp reconstruction.
- To test the ECRB and ECRL, the patient attempts wrist extension against resistance. A palpable groove, or V sign, forms between the two proximal muscle bellies if both have an MRC grade of 5 (**FIG 1**).¹
- For patients presenting with a contracture, it is important to specifically evaluate the contribution of the FDS and FDP muscles to the contracture. Examine finger extension both with the wrist in maximum flexion and in maximum extension.
 - In cases of FDS and FDP contracture, finger flexion deformity will be worse on examination with the wrist in maximum extension as compared to maximum flexion. This occurs because wrist extension tightens the flexor tendons exacerbating the deformity.
- The MCP, proximal IP, and distal IP joints should be examined to rule out joint contracture and intrinsic tightness.
 - An ulnar nerve lidocaine block during examination can help better determine the presence of intrinsic spasticity or contracture.² Spasticity will improve after a nerve block whereas a contracture will not.

FIG 1 • Test to confirm active use of the ECRL and ECRB. A V sign forms between the two muscle bellies of the wrist extensors with resisted wrist extension.

IMAGING

- If despite clinical examination, the examiner is still uncertain of whether a muscle is under volitional control, electromyography focusing on the muscle of interest helps identify spastic and flaccid muscles and determine phasic activity.

NONOPERATIVE MANAGEMENT

- Modest attempts to control the position of the hand in contracture or spasticity can be performed with serial splinting or casting.
- Phenol motor blocks may alleviate spasticity to a degree.

SURGICAL MANAGEMENT

- ECRL to FDP transfer
 - For an effective grasp, the fingers must first be able to extend to wrap around an object and then flex to grab it.
 - Unlike lateral pinch where tenodesis of the EPL can be used to extend the thumb in preparation for pinch, for grasp, and for release, the reconstruction cannot rely solely on finger tenodesis for finger extension. The presence of active finger flexion without active finger extensors will create a tendon imbalance, leading to flexion contractures.
 - Finger extension and finger flexion reconstructions have competing postoperative rehabilitation protocols. Historically, a two-staged reconstruction has been described. The ECRL to FDP transfer is typically the

second stage, whereas the extensor reconstruction is the first stage (see Finger Extension chapter). However, both stages are more frequently performed simultaneously, particularly in a more frail and elderly patient who may not tolerate multiple operations with multiple periods of immobilization.

- Before active grasp reconstruction, the priority is to first ensure the patient has active elbow and wrist extension. Therefore, only patients with ICT grade 3 or higher have sufficient donor muscles for reconstruction.
- ECRL to FDP transfer is indicated in patients who require active finger flexion and have good active wrist extension with supple wrist and PIP joints.
- Wrist extension occurs synergistically with finger flexion, making the ECRL an ideal motor for transfer to the FDP. Postoperative learning and rehabilitation is simpler than with other nonsynergistic transfers. Additionally, active wrist extension will shorten the flexors via tenodesis. The ECRL to FDP transfer takes advantage of this biomechanical principle by enhancing FDP flexion with wrist extension and providing an additional 2 cm of tendon excursion.³

■ STP transfer

- The STP transfer is indicated in patients with severe spasticity or in patients with an established contracture of the forearm musculotendinous units, resulting in fixed finger flexion contracture.⁴
- The patient typically has no functional use of the fingers and often suffers from hygiene problems with skin maceration and nonhealing palmar wounds.
- The goal of the procedure is to position the hand in a more functional posture, facilitating hygiene and personal care, without leaving the patient with flaccid fingers.
- The procedure alleviates contracture by transecting the finger flexors but still maintains wrist balance by transferring the FDS to the FDP tendons (**FIG 2**). The STP transfer can be performed with concomitant lengthening of wrist and thumb flexors when necessary, to achieve a position of balance between the wrist and digits.⁴

■ Zancolli lasso procedure

- The Zancolli lasso procedure is indicated in patients with clawing or an intrinsic minus deformity of the digits.
- As originally described by Zancolli, the lasso procedure results in a dynamic passive tenodesis causing MP flexion with active wrist extension. This augments grasp by initiating the first stage of grasping: MP flexion.
- Patients with a concurrent PIP flexion deformity from FDS spasticity further

benefit from the lasso procedure by releasing the FDS as the spastic deforming force and transferring it into an MP flexor.

- The lasso procedure can also be performed prophylactically to prevent MP joint hyperextension and clawing with finger extension.
- Taking advantage of the tenodesis effect, the lasso procedure is also effective in patients with a paralyzed FDS.

FIG 2 • FDS to FDP transfer. **A.** Finger flexion deformity involving both the FDS and FDP muscles. A transection is made in the proximal FDP and the distal FDS. **B.** The wrist is extended and the proximal end of the FDS is transferred to the distal end of the FDP to re-establish wrist balance and permit finger flexion.

Preoperative Planning

- It is imperative to confirm that the patient is not entirely dependent on the ECRL for wrist extension prior to its use for transfer. The V sign confirming the presence of a strong ECRL and ECRB on physical exam is very reliable, but if there is any doubt, the surgeon should leave the ECRL intact (see **FIG 1**).

- Prior to an STP transfer, confirm that the MCP and IP joints are supple. If joint contracture is present, the transfer alone will do little to improve the flexion deformity. The patient may need additional procedures such as closed manipulation, capsulotomies, or joint fusions.
- Following an STP transfer, the patient will continue to have limited finger motion. The purpose of the operation is to improve finger position for better hygiene, not function. This should be clearly discussed with the patient and caregivers before surgery.
- If an anterior elbow release is also planned, perform the release prior to the FDS tendon transfer. This will facilitate positioning the forearm, simplifying exposure and visualization for STP transfer.

Positioning

- The patient is placed in the supine position with the arm extended on an arm board. A nonsterile upper arm tourniquet is applied to provide a bloodless operative field. General anesthesia can help provide maximum muscle relaxation.

Approach

- Various approaches are possible, and multiple incisions are often required.
- The ECRL can be transferred to the FDP around the radial border of the radius or through the interosseous membrane. An advantage of transfer around the radius is that the line of pull provides secondary forearm supination.
- The Zancolli lasso is an intrinsic reconstruction that is an adjunct to the extrinsic tendon reconstruction. It can be performed during either of the two stages of hand reconstruction (extensor or flexor stage).
- For the Zancolli lasso procedure, a single transverse incision or separate zigzag incisions can be made across the MP flexion creases. The lasso can be performed with the FDS of each individual finger used as a lasso or splitting the slips of the FDS of the middle and ring finger to lasso around the index/middle and the ring/small fingers, respectively. Another technique involves taking only the middle finger FDS tendon and splitting it into four slips to be used for all the fingers.⁵

TECHNIQUES

■ Extensor Carpi Radialis Longus to Flexor Digitorum Profundus Transfer for Active Finger Flexion

- Make an 8- to 10-cm longitudinal dorsal incision (**TECH FIG 1A**).
- Identify the extensor carpi radialis longus (ECRL) and the extensor carpi radialis brevis tendons (ECRB). Identify and protect the superficial radial nerve (**TECH FIG 1B**).
- Sharply transect the ECRL tendon as distal as possible at the level of its insertion on the index metacarpal and deliver it proximal to the extensor retinaculum.
- Dissect the ECRL as far proximal as possible to maximize its excursion and to provide a straight line of pull for its new insertion.
- Make a volar incision to identify the FDP tendons at its musculotendinous junctions at the wrist crease (**TECH FIG 1C**).
- Pass the ECRL tendon under the radial vessels into the volar forearm and perform a Pulvertaft weave in an end-to-end fashion to the flexor digitorum profundus tendons with 2-0 nonabsorbable braided sutures (**TECH FIG 1D**).
 - Be certain to include the FDP tendon to the index finger. It often is separate from the remaining digital profundus tendons and can easily be missed in the transfer.⁶
- Set the tension with the wrist in maximal tension. The fingertips should touch the palm with the wrist in full passive extension after tendon transfer.⁷
- If a Zancolli lasso procedure is also part of the reconstruction plan, perform it before ECRL transfer (either as a first-stage procedure or just before the ECRL transfer). The tension can be better gauged in this manner.
 - After the lasso procedure is complete, set the ECRL tension with the finger MP joints at 0 degrees when the wrist is at neutral. With the wrist in extension, the MP joints should flex 30 to 40 degrees.
- Release the tourniquet and achieve hemostasis. Close the incisions primarily.

TECH FIG 1 • **A.** Dorsal incision for exposure of the extensor tendons. **B.** Identification of the ECRL tendon. **C.** Volar incision for exposure of the FDP tendons. **D.** Transfer of the ECRL tendon in the volar direction and completion of a Pulvertaft weave with the FDP tendons. Left, distal; right, proximal.

■ Flexor Digitorum Superficialis to Flexor Digitorum Profundus Transfer (Superficialis to Profundus Transfer)

- Identify the FDS and FDP tendons through a volar forearm incision (see **TECH FIG 1C**). Take care to avoid injury to the median nerve and the ulnar neurovascular bundle.
- Identify the palmaris longus, and perform a tenotomy proximally.
- Flex the wrist and identify the tendons of the FDS to the index, long, ring, and small fingers. Proximal to the transverse carpal ligament, suture all the FDS tendons together with a running, locking, nonabsorbable suture creating a single tendon unit.
- Sharply transect the FDS tendons at the level of the wrist distal to the suture

line (**TECH FIG 2A**).

- Retract the FDS tendon unit proximally exposing the FDP tendons. In a similar fashion, create a single tendon unit across the most proximal convergence of the FDP tendons to the index, long, ring, and small fingers. This location is approximately 10 cm proximal to the wrist crease. Sharply transect the FDP tendons proximal to the suture line (**TECH FIG 2B**).
- Extend the wrist and fingers, and note that the distal ends of the cut FDP tendons migrate distally.
- Suture the proximal FDS tendon unit to the distal FDP tendon unit with a nonabsorbable braided suture. Set the tension with an assistant holding the wrist and the fingers in maximum extension (**TECH FIG 2C**).
- Confirm that there is corrected finger extension and presence of the normal finger cascade.
- Release the tourniquet and achieve hemostasis. Close the wound primarily.
- Place a postoperative splint with the wrist in 20 degrees of extension and fingers in 20 degrees of flexion at the metacarpophalangeal and interphalangeal joints.

TECH FIG 2 • A. The tendons of the FDS are sutured together at the level of the wrist creating a single tendon unit. The tendons are ligated distal to the suture line. **B.** The sutured FDS unit is retracted proximally, and the FDP is identified. Approximately 10 cm proximal to the wrist crease, the FDP tendons are

sutured together. The tendons are ligated proximal to the suture line. **C.** The hand is extended and the distal end of the FDP unit will migrate distally. The proximal end of the FDS is sutured to the distal end of the FDP.

■ Zancolli Lasso Procedure

- Make zigzag incisions on the palm and proximal digits to expose the flexor tendon sheaths from the middle of the metacarpal to the middle of the proximal phalanx. Take care to avoid injury to the neurovascular bundles.
- Identify the proximal and distal limits of the A1 pulley.
- Using a forceps, apply tension to the A1 pulley, simulating transfer, to determine whether the MP joint will be pulled into flexion.
 - If the MP joint cannot be pulled into flexion, include a portion of the A2 pulley in the transfer.
- Open the tendon sheath distal to the A1 pulley with an L-shaped incision.
- Flex the finger and identify the two slips of the FDS (**TECH FIG 3A**). Place a suture in the FDS to minimize proximal retraction with ligation.
- Divide both slips of the FDS tendon as far distally as possible. Use the suture in the FDS to help minimize handling of the FDP tendon and potential postoperative adhesions.
- Pull the FDS slips through the opening in the pulley sheath. Ensure that both slips of the FDS are free from all surrounding attachments, including the synovial sheath and vincula (**TECH FIG 3B**).
- Repeat the same procedure for each finger.
- Loop the FDS tendons back over the pulley sheath in a palmar and proximal direction. Suture the FDS tendon to itself using a 4-0 nonabsorbable suture in an interweave fashion (**TECH FIG 3C**).
- After inserting the first suture, confirm that there is appropriate tension by observing the MP motion to passive tenodesis.
 - When the wrist is extended, the MP joints should flex with a uniform cascade.
 - When the wrist is flexed, the MP joints should extend fully without hyperextending.
- Adjust the tension as necessary. Typically, the tension is increased gradually

from the index to small fingers to restore a physiologic cascade.³

- Confirm that the position of the index finger's MP joint will continue to permit key pinch with the thumb.
- Release the tourniquet and achieve hemostasis. Close the wounds primarily.
- Place the patient in postoperative immobilization with the wrist in 20 to 30 degrees of flexion, MP joints at 60 to 70 degrees of flexion, with the PIP and DIP joints free for 4 weeks.

TECH FIG 3 • A. The two slips of the FDS tendon are identified distal to the A1 pulley. The slips are ligated as distal as possible. **B.** The FDS tendon is pulled through the opening in the flexor sheath after ensuring that it is not tethered by the synovial sheath or vincula. **C.** The FDS tendon is looped around the A1 pulley in a palmar and proximal direction. It is sutured to itself forming a lasso around the A1 pulley.

PEARLS AND PITFALLS

General	■ Release the tourniquet and check for hemostasis prior to wound closure for the STP transfer. There are multiple perforators from the ulnar artery to the FDP that can easily be missed. ■ The median nerve can easily be mistaken for a flexor tendon under tourniquet control. A gentle exsanguination will preserve the longitudinal neural blood supply, making it easier to correctly identify and protect the nerve.
ECRL to FDP transfer	■ Patients must have strong wrist extension and not be solely dependent on the ECRL for wrist extension. ■ Identify the tendons of both the ECRL and the ECRB prior to transection to avoid injury to the ECRB. ■ Be certain to identify and include the FDP tendon to the index finger.
FDS to FDP transfer	■ Before closure, confirm that there is no excess tension on the neurovascular structures. This can limit the length of contracture release. ■ Create a single tendon unit of the FDS and FDP prior to transection to maintain the normal finger cascade. ■ Excursion of the median nerve may be a limiting factor for the amount of contracture release that can safely be attained.
Zancolli lasso procedure	■ If the small finger FDS is vestigial, the ulnar slip of the ring finger FDS can be used for the lasso.

POSTOPERATIVE CARE

- Following the ECRL to FDP transfer, the patient remains immobilized for 4 weeks until the tendon junctures have healed.
 - At that point, the patient begins mobilization and training with occupational therapy.
- After the STP transfer, the wound is examined at 10 days and sutures are removed.
 - The patient remains immobilized for another 4 weeks. Active finger flexion and extension can then begin, but the patient is to remain in a splint when not undergoing hand therapy or bathing.

- After 4 weeks, the patient can transition to a nighttime splint for 3 to 6 more months.
- After the Zancolli lasso procedure, patients begin immediate daily therapy with passive range of motion of the IP joints.
- After 4 weeks, convert the patient to a nighttime resting splint in the same position and active range of motion can be initiated.

OUTCOMES

- The ECRL to FDP transfer typically has good results in establishing active finger flexion.
- Following STP transfer, the majority of patients have an open position of the hand and wrist with resolution of palmar hygiene problems.^{2,4}
- Most patients have good to excellent results following the Zancolli lasso procedure with a significant improvement in grip strength.⁸

COMPLICATIONS

- In addition to typical surgical complications, rupture of the tendon repairs is a potential complication. This should be suspected if there is a sudden loss or drop of function during rehabilitation.
 - There should be a low threshold to return to the operating theater for exploration and the surgeon should be prepared to repair or revise the transfer with a tendon graft if necessary.
- If wrist extension is not properly assessed preoperatively and it is not properly established that the patient is dependent on the ECRL for wrist extension, its transfer can lead to postoperative difficulty with wrist extension.
- Following STP transfer, the risk of superficial wound infections is elevated, particularly in patients with macerated palmar skin at time of surgery.²
 - In patients with intrinsic hypertonicity, a swan-neck deformity can result if the intrinsic spasticity is not also addressed.
- FDP adhesions in the metacarpophalangeal area are common in the Zancolli lasso procedure, occasionally requiring tenolysis.

Section XIII: Congenital Hand Disorders

63 Release of Finger Syndactyly Using Dorsal Rectangular Flap

CHAPTER

Amir H. Taghinia

DEFINITION

- Syndactyly is fusion of adjacent digits (Gr. *syn* with or together + *dactylos* finger).
- Syndactyly can be congenital or acquired. This discussion focuses on congenital syndactyly.

ANATOMY

- Syndactyly can involve skin, nail, bone, nerves, vessels, and tendons.
 - It can be simple, involving only skin, or complex, involving bone and other tissues. It can also be complicated, wherein the delineation of structures belonging to different digits is difficult to differentiate (**FIG 1A**).
 - It can be complete (involving the entire finger) or incomplete (partial involvement).
 - It can also be wide or narrow (**FIG 1B**). Most authors do not discuss this issue, but it bears greatly on the operative plan for release.
- The normal interdigital web space has an hourglass appearance. It begins dorsally distal to the metacarpophalangeal joint and takes a 45-degree palmar angle. The web meets the palmar skin halfway between the metacarpal head and the proximal interphalangeal (PIP) joint (**FIG 2**).

FIG 1 • A. Four types of syndactyly are shown. **B.** Syndactyly can be wide or narrow. Wide cases provide more skin for closure and allow easier interdigitation of flaps.

PATHOGENESIS AND NATURAL HISTORY

- The exact etiology of syndactyly has not been elucidated. It is considered to be a malformation, based on the Oberg, Manske, and Tonkin classification, likely due to failure of apoptosis.¹
- Syndactyly occurs in 1 out of 2000 to 3000 births. The natural history of untreated syndactyly is dependent on the degree of involvement.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients are usually seen in infancy. The diagnosis is clear, but the involvement of deeper structures can be difficult to ascertain via physical examination alone.
- The surgeon should examine and record the web spaces involved, degree of involvement, deviation or angulation, nail involvement, and any deficits in range of motion. In most simple cases, range of motion is normal.
- The surgeon should elicit family history and determine if there are any associated medical conditions (syndromes).

IMAGING

- Plain radiographs are the study of choice, although they are rarely needed for simple syndactyly.

FIG 2 • The normal web space has an hourglass appearance with a 45-degree inclination. It meets the palmar skin halfway between the MP and PIP joints.

- Plain radiographs help delineate the degree of bone involvement and guide timing and technique of surgical release in complex and complicated cases (**FIG 3**).
- A few experts have advocated CT angiography to understand the vasculature when considering simultaneous release of neighboring web spaces,² but this is not routinely done.
- Even if simultaneous releases of adjacent digits are planned, the surgeon can make intraoperative judgment by dissecting the neurovascular bundles to preserve at least one artery to each digit.

FIG 3 • Complex third and fourth web space syndactyly. Distal phalangeal coalition causes flexion and ulnar deviation of the longer digits.

SURGICAL MANAGEMENT

- The principles of syndactyly release are dorsal flap for commissure reconstruction, volar zigzag incisions to avoid contractures across flexion creases, and use of skin grafts as needed for coverage of open wounds.
- The author plans timing of syndactyly release based on the degree of involvement.
 - Patients with distal phalangeal coalition, especially between the small and ring fingers (with or without involvement of the middle finger), can develop significant deviation and flexion contractures of the longer fingers as the distal phalanges cause tethering (see **FIG 3**). Early intervention can help relieve this problem and allow improved directional growth.
- Simple syndactyly releases can be performed between 1 and 2 years of age. To relieve tethering and deviation, earlier release around 9 months is advocated. The decision to operate early has to be carefully weighed against possible long-term consequences of general anesthesia early on in childhood.
- The decision to use skin grafts, whether they should be split or full thickness,

and the places from which to harvest them have been hotly debated in the literature.^{3,4} A number of surgeons have presented different techniques for release without use of skin grafts.

- The author prefers to use of full-thickness skin grafts in most syndactyly release procedures. Syndactyly is a problem of missing skin. Skin grafting provides the best possible release and widest web space.
- The author takes full-thickness grafts from the lower abdomen (not the groin). This area provides ample skin for subsequent releases if there is multiple web involvement and heals nicely.
- Bilateral syndactyly release procedures are performed routinely in infants and toddlers.
- Neighboring web space releases are not performed simultaneously; they are staged about 6 to 9 months apart.
- Vascular insufficiency concerns alone do not inform this practice; rather, skin deficit on both sides of a finger makes closure more difficult.

Preoperative Planning

- Review radiographs again.
- Discuss risks, benefits, and expectations again with parents on the day of surgery. Specifically outline the risks of dense scarring, flap or graft loss (partial or complete), future web creep, and hyperpigmentation of skin grafts (especially in those with Fitzpatrick skin type IV and above).

FIG 4 • Draping of lower abdominal donor site for skin graft.

Positioning

- The patient is positioned supine with the arm out on a small hand table.
- The lower abdominal area for the skin graft is squared off with Steri-Drapes (**FIG 4**).

Approach

- Incisions are planned carefully prior to use of the tourniquet. The majority of the “case” is incision planning. The markings dictate where flaps will transpose and where skin grafting is needed.

- In cases where skin is deficient and dorsal and palmar flaps will not interdigitate, the author plans a dorsal straight-line release (**FIG 5**) and zigzag volar incisions (if flexion creases are present) as outlined above. This approach creates more open wounds to skin graft.
- Dorsal and volar incisions are made for every syndactyly release. Conjoined bones and neurovascular bundles are best approached dorsally.

FIG 5 • When the syndactyly is very narrow (usually due to bone fusion) and/or multiple adjacent web spaces are

involved—such as in this patient with type I Apert syndrome—there is not enough skin to allow the dorsal and volar triangular flaps to interdigitate. Accordingly, a straight-line dorsal release is planned. In the case shown, adjacent rectangular commissure flaps (for both third and fourth web spaces) would remove too much skin from the nonborder digits; accordingly, triangular flaps were planned.

TECHNIQUES

■ Dorsal Rectangular (Hourglass) Flap for Syndactyly Release

Dorsal Markings

- Mark the metacarpal head pit for each neighboring digit. Draw an hourglass-shaped flap with the distal straight-lined, transverse incision located two-thirds to three-fourths of the distance between the metacarpal head and proximal interphalangeal joint (**TECH FIG 1A**).
- The palmar border of the normal web space lies about halfway between these two anatomic landmarks (see **FIG 2**).
 - Planning the flap's distal extent beyond the halfway point allows it to rotate about its axis proximally (at the metacarpal heads) and reach just proximal to the ideal location of the web space.
- Mark the extension creases with transverse or slightly oblique lines.
 - In complete and near-complete syndactyly cases, draw these lines from (just shy of) the midpoint of one finger to the other (**TECH FIG 1B**). In incomplete cases, these lines can be shorter (**TECH FIG 1C**).
 - Connect the lines via oblique lines that create the least acute angle to allow for optimal blood flow to the flap. The reason for longer flaps in narrower cases is not additional skin (the amount of skin remains fixed) but greater flexibility in maneuvering the flaps.

TECH FIG 1 • Dorsal hourglass commissural flap markings **(A)** with extensions for complete syndactyly **(B)** and incomplete syndactyly **(C)**.

Volar Markings

- Draw a transverse line 2 to 3 mm proximal to the mid-proximal phalanx flexion crease (**TECH FIG 2A**).
 - A small triangular dart in the middle of this line helps to break up the web scar.
- Mark the flexion creases similarly to the extension creases on the dorsum.
 - Similar to the dorsal markings, the extension of these transverse lines is dictated by the degree of involvement. These are then connected via oblique lines similar to the dorsal oblique markings (**TECH FIG 2B, C**).
 - Ensure that the dorsal and volar flaps are designed such that they will interdigitate once raised.

Flap Creation

- Exsanguinate the upper extremity.
 - In infants and toddlers, an Esmarch bandage is used as a tourniquet because it is more effective at providing a bloodless field in small arms (**TECH FIG 3**). The technique is controversial, as the pressure is not known; however, with experience, the surgeon can perform it predictably and safely in cases of short duration.
 - In older children, a standard pneumatic tourniquet is used.
- Raise the dorsal flap in the subcutaneous plane leaving 2 to 3 mm of fat on the flap (**TECH FIG 4A**).
- Raise the remaining dorsal and volar flaps. Raise the dorsal flaps on the

extensor mechanism. Raise the volar flaps subcutaneously.

- Approach the web space with fine scissors and forceps. Spreading helps define the neurovascular structures (**TECH FIG 4B**).
 - Any interdigital bands/fascia should be excised.
 - Defat the fingers as needed, protecting the neurovascular bundles, to allow for the dorsal and palmar flaps to transpose.
- Split the dorsal flap down the midline to allow inset (**TECH FIG 4C**). The dorsal flap insets into the dart on the volar side (**TECH FIG 4D**).
 - By design, two volar flaps on either side of the web are created (see **TECH FIG 4D**), which are sutured to either edge of the dorsal flap thereby dividing the web scar even more.
- Mobilize, trim, and appropriately inset the dorsal and palmar flaps.

TECH FIG 2 • Volar markings with small dart to break up web scar (**A**) and for complete syndactyly (**B**) and incomplete syndactyly (**C**).

Grafting

- Use suture foil to create templates of the resultant defects for skin grafting (**TECH FIG 5A, B**).
- Release the tourniquet and obtain hemostasis. The author uses the bipolar electrocautery for bleeding in the skin graft bed only.

TECH FIG 3 • Technique of applying Esmarch bandage as tourniquet. In small children, the standard 3-in. Esmarch bandage is too wide. **A.** It is trimmed to about 2 in. long by using a no. 10 blade. It is then rolled out, and about one-third of its length is cut off and discarded to decrease its bulk (not shown). It is then wrapped around the extremity (**B**) and secured at the upper arm (**C–E**). Tightness is gauged by using the thumb (**C**).

TECH FIG 4 • A. Dorsal flap raised in the subcutaneous plane. **B.** Spreading to divide soft tissue in the web with fine instruments. Dorsal flap split (**C**) and inset (**D**). The dorsal flap insets into the previously created volar dart (*white arrow*). The two volar flaps on either side of the web (*black arrows*) are sutured to either edge of the dorsal flap thereby breaking up the web scar.

TECH FIG 5 • A. With the dorsal flap and digital flaps fully inset, the dorsal view shows the remaining skin defects and foil templates. **B.** Palmar view. **C.** Foil templates outline a lenticular excision centered on a lower abdominal skin crease. Dorsal (**D**) and web space (**E**) views after inset of skin grafts.

- Skin edge bleeders usually stop when the skin grafts are applied.
- Mark a transverse crease in the lower abdomen for skin graft harvest. Avoid areas near the midline to prevent subsequent hair growth. A crease just below the anterior superior iliac spine provides ample skin, is well hidden, and heals beautifully.
 - Transpose the foil templates to this area and mark out a lenticular excision (**TECH FIG 5C**).
- With assistants holding traction, harvest a thin full-thickness skin graft. With enough traction, one can use the blade alone to harvest a graft that requires no defatting.
- Apply the skin grafts (**TECH FIG 5D,E**). The author uses 6-0 chromic sutures.
 - The grafts have elasticity in multiple dimensions, so the surgeon must take care to apply them under appropriate tension and disallow pleating and redundancy of the graft.
 - Running horizontal mattress sutures provide the best appearance on the dorsum.

Dressing and Immobilization

- Dressings and immobilization are critical to predictable healing (**TECH FIG 6**).
- Antibiotic-impregnated gauze is applied to incisions and grafts. Gauze wrap and cotton packing are used in the web space help to provide compression on the grafts.
- The limb is immobilized in a well-padded long-arm mitten cast for 3 weeks.
 - Slip on a long 2-in. stockinette and apply the padding high up to the shoulder with the elbow at 90 degrees.
 - Apply the cast with the fingers buried but the thumb exposed.
- Infants between 9 and 15 months of age, especially those with significant subcutaneous fat, are notorious for slipping out of their casts. One can minimize this by taking several steps:
 - Extend the cast high up to the shoulder (but avoid compressing the vessels in the axilla).
 - Apply skin adhesive (such as Benzoin or Mastisol) to the arm and forearm prior to placing the stockinette.
 - Mold the cast to create a well-defined 90-degree angle on the posterior aspect of the elbow as the arm meets the forearm. Additionally, mold the

cast to the contour of the underlying skeleton with a supracondylar and proximal forearm “squeeze.”

- Finally, leave the thumb out and instruct parents to call if the thumb slips into the cast.

TECH FIG 6 • Dressing supplies needed include antibiotic-impregnated gauze (in yellow), 4 × 8 gauze sponges cut longitudinally into thirds for wrapping the digits, cotton for compression in the web, and cling and Webril wraps.

PEARLS AND PITFALLS

Surgical management

- Syndactyly can be narrow or wide. This bears on surgical planning because wide syndactyly has more skin for transposition. It is important to ascertain how much skin is available in the web preoperatively.

Exsanguination

- Regular pneumatic tourniquets are not effective in small

and tourniquet	children—the Esmarch bandage works better. The surgeon must be careful not to make the tourniquet too tight.
Release	■ The most proximal extent of release is the bifurcation of the arteries. A distal nerve bifurcation can be teased apart with gentle intraneural dissection and splitting of the fascicles. Occasionally, one will encounter an arterial bifurcation that is too distal. In these instances, the smaller branch can usually be sacrificed depending on the blood supply to the other side of the digit. One can place a microvascular clamp, release the tourniquet, and assess vascularity before dividing any branches.
Postoperative	■ Adequate compression and immobilization is critical to successful skin graft take and predictable healing. Children between 9 and 12 months of age occasionally will slip out of long-arm casts; these should be reapplied promptly.

POSTOPERATIVE CARE

- Immobilize the arm for 3 weeks as noted previously. If the cast falls off, it should be replaced.
- Remove the cast in the office and assess healing of skin grafts. Sutures, old clots, and debris can be removed from the wounds at this time.
- Occupational therapy to make nighttime volar resting thermoplast splints with web space conformers at this time. The conformers put pressure on the scars and allow them to soften and settle more quickly. These should be worn for about a month after the cast is removed.

OUTCOMES

- Functional outcomes after syndactyly release depend mostly on the preoperative status of the digits and the hand.
- In simple cases where the joints are not involved, full range of motion of the involved digits should be expected postoperatively (**FIG 6**).
- In complex cases, reconstruction is difficult and common postsurgical functional issues include rotational and angular deformity and nail deformity.⁵

COMPLICATIONS

- Web creep (loss of initial depth of the web space) can occur over time, with incidence ranging from 2% to 24% (**FIG 7**).⁴
- Web scars are best corrected right before the child starts school, around 5 or 6 years of age, after a significant growth spurt has occurred and the scars have

had ample time to soften.

- Most webs scars respond well to Z-plasty, but occasionally, skin grafting may be necessary.
- Skin graft loss or flap loss, partial or complete
- Vascular compromise—especially in complex and complicated cases
- Nail deformity
- Rotational and angular deformities
- Dense scars

FIG 6 • Long-term postoperative dorsal (**A**) and web space (**B**) views of the patient with complete third web space syndactyly in TECH FIGS 1B and 2B. Patient has a pliable web space with no limitations in range of motion or function. Three-month postoperative dorsal

(C) and web space (D) views of the patient with incomplete fourth web space syndactyly in TECH FIGS 1A and 2A. Early healing with good maintenance of web and normal function.

FIG 7 • Web space scar after syndactyly release. **A.** Three years after syndactyly release, this child has a scar that tethers the web space and prevents full extension of the ring finger. **B.** Twenty years after syndactyly release, this adult patient has a web scar that is bothersome but does not interfere with function. Note desquamation of scarred skin.

64 Hypoplastic Thumb Reconstruction

CHAPTER

Amir H. Taghinia

DEFINITION

- A thumb is considered hypoplastic if any of its osseous, musculotendinous, or articular components is deficient or missing or if the web space that it forms with the index finger is shallow.

ANATOMY

- The normal thumb is broad with osseous and articular structures that allow ample movement in multiple planes. Its intrinsic muscles provide a short moment arm, powering the motion enabled by the ossearticular column. The normal first web space has a gentle curve spanning from the thumb metacarpophalangeal (MP) joint to the index finger MP joint.
- The modified Blauth classification system¹ provides a surgically useful basis for categorizing thumb hypoplasia.
 - Type I thumbs have minimal shortening and narrowing. No surgical intervention is needed.
 - Type II thumbs have narrowing of the first web space, hypoplastic intrinsic thenar muscles, and laxity of the MP joint. Reconstruction is recommended.
 - Type IIIA thumbs have features seen in type II thumbs, but they also have extrinsic tendon anomalies and a hypoplastic metacarpal. Reconstruction is recommended.
 - Type IIIB thumbs have features seen in type IIIA thumbs, but they also have an absent proximal metacarpal and instability of the carpometacarpal (CMC) joint. Pollicization is the treatment of choice.
 - Type IV (*pouce flottant*, floating thumb) and V (*aplasia*, complete absence) thumbs are also best treated with pollicization—these thumbs are discussed

in the chapter on Index Finger Pollicization.

- Specific anatomic deficiencies in types II and III thumbs include the following^{1–3}:
 - Laxity of the MP joint ulnar collateral ligament (UCL). The radial collateral ligament (RCL) may also be lax, as may the entire joint capsule (global laxity).
 - Hypoplasia or absence of the thenar muscles manifested as poor opposition
 - The flexor pollicis longus (FPL) tendon may be eccentrically attached to the distal phalanx. But it also may be absent, may follow an abnormal path (usually radially transposed), may have a very distal muscle belly, or may anomalously attach to the proximal phalanx.
 - The extensor pollicis longus (EPL) tendon may also be eccentrically attached to the distal phalanx. It may also be absent or follow an abnormal, more radial path.
 - Abnormal radial interconnections between the EPL and FPL lead to a characteristic radial deviation of the thumb termed pollex abductus. These connections are usually present at the MP joint and prevent active interphalangeal (IP) joint motion.
- The distinction between type II and IIIA may not bear strongly on the choice of surgical intervention, as there can be some overlap. If the thumb requires web space deepening, collateral ligament reconstruction, and opponensplasty, then there is usually some degree of extrinsic tendon abnormality present.² The surgeon should focus on treating the individual deficiencies that are present in a given thumb.

PATHOGENESIS

- Thumb hypoplasia occurs as a result of multiple potential factors—including genetic (associated syndromes), environmental, teratogenic (thalidomide), and idiopathic causes.
- It is considered to be a malformation, based on the Oberg, Manske, and Tonkin classification of 2010.⁴

NATURAL HISTORY

- Thumb hypoplasia occurs in 1 out of 100 000 live births. A large number of patients with thumb hypoplasia will have associated conditions such as cardiac or hematologic anomalies.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with type I to IIIA can present anytime in life. In milder cases, the differences can be so subtle that parents do not notice a mild deficiency (in function or appearance) until much later in life, especially if the nondominant side or both sides are involved.
- Physical findings:
 - Intrinsic thenar muscle hypoplasia (**FIG 1A**). This finding is usually evident early, especially if there is a comparative normal contralateral side. Patients lack strong opposition.
 - MP joint instability (**FIG 1B,C**). The stability of this joint is difficult to assess in an infant because of global joint laxity. However, as the child grows, the laxity becomes more evident on examination. Patients sometimes use a “metacarpal grasp”—when an object is held between the fingers and the thumb metacarpal head, thus avoiding the distal thumb.

FIG 1 • A. Palmar view of hand with thumb hypoplasia. The thumb is short with flattening of the thenar eminence and lack of flexion or extension creases at the IP joint. The RCL **(B)** and UCL **(C)** are lax, allowing significant deviation of the joint. **D.** The first web space is shallow; radially deviating the thumb any more to widen the web space would result in deviation at the MP joint rather than splaying of the metacarpals.

- Shallow web space (**FIG 1D**). This finding is also evident early, though the degree of involvement is assessed subjectively. An incompetent UCL can sometimes mask a shallow web space. It is best to assess the web space by the angle achieved between the index and thumb metacarpals.
- Extrinsic muscle abnormalities. These include abnormal size, length, strength, and insertion of the thumb flexor and extensors. These anomalies are typically manifested as joint deviations (MP joint) and/or lack of flexion or extension creases (IP joint).
- The functional ability of the CMC joint is often not obvious on the infant's plain film radiograph. Functional differentiation can be made by allowing the child to grow and watching the toddler at play. If the thumb is bypassed in favor of the index finger, the joint is likely nonfunctional.
- The hand surgeon should be aware of the conditions associated with thumb hypoplasia (eg, VACTERL, Fanconi anemia, and Holt-Oram syndrome) and have a low threshold to refer if suspicions arise.
- In particular, Fanconi anemia is a fatal disease that occurs mainly in those with thumb hypoplasia and is easily diagnosed with a simple blood test.

IMAGING

- Plain radiographs (**FIG 2**) help to determine the status of the metacarpal, CMC joint, any abnormalities of the index finger, and the status of the distal radius and ulna (presence of radial longitudinal deficiency).

NONOPERATIVE MANAGEMENT

- Most patients with Blauth type I thumb hypoplasia do not need surgical intervention.

FIG 2 • Plain radiographs of both hands demonstrate a comparatively shorter right thumb with thinner first metacarpal.

SURGICAL MANAGEMENT

- The author performs hypoplastic thumb reconstruction around 2.5 to 3 years of age, particularly if MP joint ligament reconstruction is needed. The metacarpal head should be big enough to allow creation of a tunnel without fracturing. Key procedures are outlined below.
- Opponensplasty
 - In congenital cases, opponensplasty is done using the flexor digitorum superficialis (FDS) tendon to the ring finger or the abductor digiti minimi (ADM).
 - The FDS is advantageous because it provides simultaneous opponensplasty *and* ligament reconstruction.
 - The ADM is used in patients who have had previous pollicization procedures (and have weak opposition) or those with thumb hypoplasia who do not need ligament reconstruction.

■ MP joint ligament reconstruction

- This procedure is done with tightening of the existing capsular tissues or extrinsic reconstruction with either the FDS to the ring finger (in cases that need simultaneous opponensplasty) or the palmaris longus tendon. In cases of global laxity, chondrodesis or epiphyseal arthrodesis is advocated, though both of these procedures have significant downsides.
- The author errs toward stability. Thus, for most cases, both UCL and RCL are reconstructed using a tendon graft. The tendon is split, and one-half is routed through a tunnel made in the metacarpal head to reconstruct the UCL. The tendon is then passed underneath the adductor aponeurosis and routed from dorsal to palmar through a tunnel in the periosteum in the proximal phalanx. It is then passed under the aponeurosis once again before being sutured back to itself at the metacarpal head. The RCL is reconstructed on the radial side using a similar method.
- Web space deepening.
 - This procedure is best done with a four-flap Z-plasty.
 - Multiple other procedures have been proposed, but the Z-plasty remains the workhorse for this condition.
- Other adjunct procedures include correction of MP and IP joint deviation by division of the tendinous attachments of the flexor to the extensor (pollex abductus), division of the musculus lumbricalis pollicis, step-lengthening of the extrinsic flexor tendon, and detachment and reinsertion of the EPL and/or FPL tendon.
 - Pin fixation is advocated after these procedures.
- Depending on the degree of involvement and interventions planned, it is important to establish a logical sequence for performing these procedures. For example, performing the web space release first releases the investing tight fascia of the intrinsic muscles, thus allowing better palmar abduction prior to opponensplasty.

Preoperative Planning

- Discuss risks, benefits, and expectations with parents on the day of surgery.

Positioning and Approach

- The patient is positioned supine with the arm out on a small hand table.
- Incisions are planned carefully prior to use of the tourniquet.
- Plan all incisions before exsanguinating the upper extremity.

- In toddlers, an Esmarch bandage is used as a tourniquet as it provides better hemostasis. In older children, a pneumatic tourniquet works best.

TECHNIQUES

■ Four-Flap Z-Plasty for First Web Space

- Splay the web with the help of an assistant and draw a transverse line across the tightest area of the web. On the thumb side, draw a perpendicular line dorsally. On the index finger side, draw a perpendicular line palmarly. Bisect these 90-degree angles with two additional lines at 45 degrees.
 - The five lines that are drawn should be the same length (**TECH FIG 1A–C**).
- Incise the limbs and raise the flaps with a few millimeters of fat to preserve the blood supply.
- Spread in the web space, and define and protect the neurovascular structures. Bluntly dissect the muscles and sharply divide their investing fascia to widen the distance between the index and thumb metacarpals (**TECH FIG 1D**).
 - Releasing the fascia of the adductor pollicis and first dorsal interosseous muscle is critical to obtaining a wide web space.
- If designed correctly, the flaps should transpose into their new respective positions.
- If performing a ligament reconstruction, extend the ulnar skin incision to fully expose the MP joint.

TECH FIG 1 • A–C. Designing the four-flap Z-plasty. The dorsal incision perpendicular to the web should be next to the thumb; the alternative approach would place the incision on the volar thumb and cause a flexion contracture. **D.** The investing fasciae of the adductor pollicis and first dorsal interosseous are seen in the first web space. These should be sharply divided or excised to allow optimal widening of the web.

■ Opponensplasty and Ligament Reconstruction Using FDS

Markings

- Design a radial mid-lateral incision on the thumb MP joint, just dorsal to where the glabrous skin meets the nonglabrous skin.
- Design a transverse incision over the distal wrist flexion crease; this incision should be long enough to gain access to the flexor carpi ulnaris (FCU) tendon ulnarly and the ring finger flexor digitorum superficialis (FDS) tendon radially.

- Finally, design a longitudinal A1 pulley incision in the distal palm over the ring finger ray (**TECH FIG 2**).

TECH FIG 2 • Design of the incisions, palmar view.

Exposure and Tendon Harvest

- Incise the wrist crease incision. Find and isolate the FCU tendon while identifying and protecting the ulnar artery and nerve.
- Find and isolate the FDS tendon to the ring digit at the wrist. It is usually the most palmar and ulnar flexor tendon.
 - Retract the tendon and confirm that it flexes the ring proximal interphalangeal (PIP) joint. Free its distal attachments.
- Incise the A1 pulley incision over the ring finger, spread down to the tendon sheath, and sharply divide the A1 pulley. Using a small retractor, pull the FDS up into the wound with the finger in maximal flexion.
- Obtain maximal exposure in the wound, and free the FDS from the FDP in both directions. Incise the two limbs of the FDS as distally as possible,

leaving its insertion intact.

- Occasionally, the FDS tendons of the ring and little digits are joined proximally. If pulling on the ring FDS causes flexion of the little digit PIP joint, a separate incision to release the little finger FDS may be necessary (**TECH FIG 3A**).
- Deliver the FDS into the wrist wound, and wrap with moist gauze so it does not desiccate.
- Incise the radial thumb incision and dissect to the extensor mechanism.
- If present, release the pollex abductus and free the extensor from the flexor (**TECH FIG 3B,C**).
 - It is crucial to divide these attachments, as they will otherwise act as a deforming force, stressing the MP ulnar collateral ligament (UCL) reconstruction.
 - Once released, pull the extensor and flexor proximally to ensure that the MP joint does not deviate radially.
- Correct any extrinsic tendon abnormalities. Depending on the anatomy, options include realignment of tendons with pulleys, step-lengthening, and/or reinsertion of eccentrically attached tendons. (None were performed in the example case.)

TECH FIG 3 • A. The first web space has been released and the FDS tendon has been isolated and delivered through the wrist wound. The fourth and fifth digit FDS tendons were joined up to the mid-palm, so a separate A1 pulley incision was needed on the fifth ray. **B.** Pollex abductus is radial deviation of the thumb caused by attachments of the extensor pollicis longus (EPL) tendon to the flexor pollicis longus (FPL) tendon present at the MP joint level. **C.** Extrinsic tendons can

be radially transposed and attached to each other via tendinous bands. In addition, the extrinsic tendons can have eccentrically placed insertions (radially) on the distal phalanx.

Tunnel Creation

- Retract the extensor dorsally and identify the metacarpal head on the radial side without entering the joint.
- Define the metacarpal head in the ulnar incision as well. Create a tunnel underneath the adductor aponeurosis in the proximal to distal direction. The tendon will be routed underneath the aponeurosis.
- To create the tunnel in the metacarpal head, incise the periosteum over the metacarpal head and strip off a small area. Clearly define the dorsal and palmar aspects of the metacarpal head and mark a spot exactly in the middle.

TECH FIG 4 • Multiple drill holes using a K-wire through the metacarpal head allow for creation of an elliptical tunnel through which the tendon can be

passed for ligament reconstruction.

- Make one wide tunnel by drilling multiple holes side by side using a 0.035-in. Kirschner wire (**TECH FIG 4**), then drilling in between these holes.
 - The tunnel may also be created with a single pass of a drill, appropriately selected for size.
- Ensure that the tunnel is generous and visibly larger than the tendon. Pulling the tendon through a small tunnel causes it to fray.
- The thumb metacarpal's physis is located proximally, in contrast to the physes for the finger metacarpals, which are located distally. Therefore, there are no concerns about growth arrest when this bone tunnel is created.
- Create two vertical (dorsal to palmar) tunnels in the periosteum on the radial and ulnar aspects of the proximal phalanx just distal to the physis. These tunnels should be centered volarly to best mimic the normal collateral ligaments.
 - The author does not bore vertical bone tunnels in proximal phalanges of small children. This technique is technically difficult, threatens the physis, and has not been found to be necessary.

Passing the Tendon

- Create a subcutaneous tunnel from the distal wrist incision to the radial thumb incision.
 - Loop the FDS tendon around the FCU tendon and pass it through the tunnel into the radial thumb wound.
- Pass one limb of the distal FDS through the metacarpal head tunnel from radial to ulnar (**TECH FIG 5A**).
 - Split the FDS proximally and keep pulling the tendon limb through until palmar abduction reaches about 70 degrees.
 - Suture the tendon to the periosteum on the radial and ulnar sides of the metacarpal head to secure the opponensplasty.
- On the ulnar side, pass the tendon under the aponeurosis, then dorsal to palmar through the periosteal tunnel, and then under the aponeurosis again (**TECH FIG 5B**) and suture it to the tendon itself at the metacarpal head (**TECH FIG 5C**).
- Repeat this procedure on the radial side; there is more tendon length on this side and there is no aponeurosis in the way.

- Trim any excess tendon and place additional securing sutures if necessary (**TECH FIG 5D,E**).
- Test the integrity of the ligament reconstruction to assure there is no laxity. Usually, pins are not necessary.

TECH FIG 5 • A. The FDS limbs are separated, and one is passed through the bone tunnel to create the UCL, while the other creates the RCL. **B.** The UCL is reconstructed in the shape of a triangle. The tendon is

passed superior to inferior in the periosteal tunnel and sutured back to itself. **C.** The UCL reconstruction is done under the adductor aponeurosis. **D.** RCL reconstruction is demonstrated. **E.** UCL reconstruction performed under the adductor aponeurosis.

Completion

- Close the wrist wound using several deep dermal 4-0 Monocryl sutures followed by a running 5-0 Monocryl intracuticular suture. Close the palm and radial thumb wounds with interrupted simple or horizontal mattress 6-0 chromic gut sutures.
- Transpose the Z-plasty flaps, and close the web space wounds using simple interrupted 6-0 chromic gut sutures (**TECH FIG 6**).
- Place antibiotic-impregnated petroleum gauze (Xeroform) on the wounds and apply compression gauze.
- Deflate (or remove) the tourniquet and assess perfusion.
- Apply dressings and a well-padded long-arm cast for 3 to 4 weeks.

TECH FIG 6 • Immediate postoperative palmar view shows good opposition (**A**) and a wide web space after four-flap Z-plasty (**B**).

■ Opponensplasty With Abductor Digiti Minimi (Huber)

- Design an L-shaped incision on the ulnar side of the hand (**TECH FIG 7A**).
 - The long limb of the incision should be a high mid-lateral ulnar incision extending from just distal to the fifth digit MP joint to the pisiform.
 - The short limb is a transverse volar incision on the distal wrist crease just proximal to the pisiform. This second incision helps to free the proximal origin of the abductor digiti minimi (ADM) muscle *if needed* for additional mobilization of the muscle. Note: The transfer can also be raised as a myocutaneous flap thus avoiding tunneling and adding more bulk to the thenar area.⁵
- Incise the mid-lateral ulnar marking and dissect down to the ADM muscle.

Isolate and protect any branches of the dorsal sensory ulnar nerve.

- Incise the fascia and dissect the muscle free (**TECH FIG 7B**), following it distally until its insertion is encountered on the fifth digit proximal phalanx.
- Disinsert the muscle, leaving a long cuff of periosteum attached to the muscle to facilitate subsequent reinsertion.
- Dissect the muscle proximally and identify and protect its neurovascular bundle. If additional length is needed on the muscle, the short limb of the L-incision can be made and the origin mobilized off the pisiform and flexor carpi ulnaris. The author does not transfer the origin.
- Make a high mid-axial incision on the radial aspect of the thumb MP joint and dissect down to the distal metacarpal.
- Create a generous subcutaneous tunnel between the thumb MP joint and the proximal aspect of the ulnar wound (**TECH FIG 7C**). Tunnel the muscle through.
- There are multiple sites where the muscle can now be attached: the extensor hood, the proximal aspect of the proximal phalanx, or the distal aspect of the metacarpal.
 - The author typically attaches the muscle to periosteum near the metacarpal head. This insertion site gives the most direct pull without taxing the MP joint UCL. It also avoids radial pull on the extensor mechanism, which may disrupt the learned prehensile patterns in postpollicization cases or translate the (already radially displaced) extensor tendon in hypoplastic cases.
- Attach the muscle and secure with several sutures to obtain maximal palmar abduction under moderate tension. Ensure that the pedicle is not kinked.
- Close the wounds with absorbable sutures (**TECH FIG 7D**). The ulnar incision is closed with a running intradermal suture.
- Place antibiotic-impregnated petroleum gauze (Xeroform) on the wounds and apply compression gauze.
- Deflate (or remove) the tourniquet and assess perfusion.
- Apply a well-padded long-arm cast for 3 weeks.

TECH FIG 7 • A. A 6-year-old boy who underwent left index finger pollicization for type IV thumb hypoplasia presented with weakness of palmar abduction and opposition. A high midlateral ulnar incision is planned with a transverse extension at the distal wrist crease, just proximal to the pisiform. **B.** The ADM muscle is seen as the most ulnar/palmar structure deep to the skin. **C.** The ADM muscle has been mobilized. A generous tunnel housing a Penrose drain connects the ulnar incision to the mid-lateral incision on the radial aspect of the neothumb “MP joint.” **D.** The muscle has been tunneled and inset in maximal palmar abduction/opposition. The wounds have been closed.

PEARLS AND PITFALLS

Anatomy

- There are numerous variations of extrinsic and intrinsic muscle/tendon anatomy, including a lumbrical emanating from the flexor (so-called musculus lumbricalis pollicis), flexor that inserts partially on the proximal phalanx, joined flexor and extensor proximally, eccentric insertions, and various degrees of attachment of the FPL to the EPL. Not all of these abnormalities need to be surgically repaired.

Technique

- Radial deviation at the MP and IP joints can be improved by releasing the pollex abductor with or without step-lengthening of the flexor tendon and reinsertion of the EPL and/or FPL into a more ulnar position on the distal phalanx. Pin fixation may be necessary after this procedure to keep the joints straight.

Surgical management

- Although many parents ask the surgeon to restore active IP joint motion, this is possible only in a small subset of patients who have preoperative passive but not active IP joint motion.
- On occasion, the MP joint laxity is so severe (global) that one should consider MP joint chondrodesis or epiphyseal arthrodesis. Chondrodesis does not heal predictably, and epiphyseal arthrodesis is only possible if there is enough epiphysis to allow fusion. Both techniques shorten the thumb and stress the CMC joint.

FIG 3 • **A.** Two months postoperatively, the patient was using the opposition transfer for grasping food. Three years postoperatively, he demonstrates a stable MP joint with strong opposition (**B**) and a wide first web

space (C).

POSTOPERATIVE CARE

- Remove the cast after 3 or 4 weeks of immobilization.
- Fashion a thumb spica thermoplast splint that can be worn for 2 or 3 weeks at night for protection.
- Start range of motion exercises with hand therapy.

OUTCOMES

- Functional outcomes for hypoplastic thumb reconstruction are satisfactory if the anatomic abnormalities are appropriately treated (**FIG 3**).
 - There is a lack of good long-term data on functional outcomes, especially data that have been controlled for severity of involvement.
- The reconstructed thumb remains smaller and less powerful than the normal thumb.

COMPLICATIONS

- Immediate complications are rare. Long-term functional concerns relate to the degree of hypoplasia, correct preoperative diagnosis, and appropriate treatment.
- Persistent lack of active IP joint motion can be seen despite adequate release of the tendon adhesions.
- Inadequate release of pollex abductor attachments can cause a deforming radial force and weaken the MP joint UCL repair in the long term.
- If the collateral ligament is reconstructed dorsal to the axis of rotation, hyperextension of the MP joint may result. Ensure that the vertical tunnel on the proximal phalanx is centered volarly.

65 Reconstruction of Radial Polydactyly

CHAPTER

Amir H. Taghinia

DEFINITION

- Polydactyly refers to the presence of extra digits. Most surgeons prefer this term to duplication, as the latter implies that the partners are exactly identical, which is the exception rather than the rule.
- Radial polydactyly is the presence of extra digits involving the thumb ray. This terminology is preferable to preaxial polydactyly because the term preaxial encompasses the thumb through ring rays.

ANATOMY

- Radial polydactyly is most commonly classified using the Iowa classification system.¹ The system divides polydactyly based on longitudinal level of bone and/or joint arborization but does not account for soft tissue differences (**FIG 1**).
- Not considering small soft tissue-only (nubbin) polydactyly cases, type IV is the most common radial polydactyly (approximately 45% of cases) and type II is the second most common (approximately 20% of cases).
- Type VII radial polydactyly, which has a triphalangeal component, is further subdivided into six types.
- The Iowa classification does not include soft tissue differences and certain types of radial polydactyly. Accordingly, additional classification systems have been proposed.
- The Rotterdam system gives broader classification possibilities (including triplicate thumb) but introduces more complexity.²
- Although the thumb partners may be nearly identical, the ulnar partner is usually the more dominant one; it is larger and better developed and has greater

range of motion and strength.

- Nevertheless, both partners may exhibit findings of thumb hypoplasia, including smaller stature, poorly developed joints and tendons with lack of flexion or extension creases, joint deviations, eccentrically inserting extrinsic tendons, and abnormal or deficient intrinsic muscles.

PATHOGENESIS

- The exact etiology of radial polydactyly remains unknown. The literature suggests an imbalance between the apical ectodermal ridge (AER) and the underlying mesoderm as one cause.
- Based on the Oberg, Manske, and Tonkin classification,³ polydactyly is considered to be a malformation with abnormal formation/differentiation of the hand plate in the radioulnar axis.

NATURAL HISTORY

- Radial polydactyly occurs more commonly in those with Caucasian and Asian descent, with an incidence of 1 in every 3000 live births.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients are usually seen in infancy.
- Radial polydactyly may run in families.
- Associated conditions may occur, even Fanconi anemia, a rare condition that can be fatal if not diagnosed early.
- Examine the thumbs for flexion and extension creases, passive and active range of motion, joint stability, and strength.
- During late infancy, the child usually starts to use the more dominant thumb. It is worthwhile to see the child at play to better understand the developing prehensile patterns.

FIG 1 • Iowa classification of radial polydactyly. The distinctions are based on increasing levels of proximal divergence. The radial partner tends to be smaller and less developed.

IMAGING

- Plain radiographs are the study of choice and should be obtained for most polydactyly cases involving bone.
- Radiography resolves all uncertainty about the level and involvement of a polydactyly that may not be clear on physical examination.

SURGICAL MANAGEMENT

- Small pedunculated (“nubbin”) polydactyly is treated in the office before a month of age. Young infants are not strong enough to resist small procedures, and they can be soothed easily with a pacifier or sugar water.
- Suture ligation can leave a small bump, so two alternatives are preferred, both using local anesthesia in the clinic treatment room: excision and suture closure or clipping at base with a hemoclip and excision. Both options are offered to the parents in this early age.
- The advantage of the clipping is that it is quick, but the clip can stay several weeks and cause local skin irritation, and there is a small risk of ingestion (especially on the radial side) if not covered with a dressing at all times.
- The excision and closure option takes more time but with likely fewer potential complications.
- For older infants or those in whom the polydactyly has a wide base, the author prefers excision in the operating room under general anesthesia at about 9 to 12

months of age.

- General anesthesia is also required in cases with more extensive involvement. No clear consensus exists regarding timing of repair. The risk of anesthesia in a small child should be weighed against early repair that takes advantage of brain plasticity. Other medical comorbidities should be taken into account.
- Small object grasp in the infant starts around 9 months of age; accordingly, the author prefers to correct polydactyly between 9 months and 1.5 years of age.
 - For very complex cases, it is worthwhile to delay repair until the structures are large enough to conduct a more technically precise operation. An example is a small trapezoidal or delta phalanx that requires a closing wedge osteotomy (eg, triphalangeal thumb).

Surgical Options

- There are three methods for repair of radial polydactyly: resection and reconstruction, the sharing technique, and acral transposition (“on-top plasty”).
 - The surgeon should not apply one technique to one type of polydactyly based purely on algorithm.
 - Instead, a careful analysis of the clinical and radiographic findings, as well as expected functional outcome and patient factors, should dictate the choice of reconstruction.
- The main principles for repair are ablation of nonfunctional structures, creation of the best functional and aesthetic single digit from parts of both partners, and preservation of length, stability, and a wide first web space.

Resection and Reconstruction

- Resection and reconstruction involves resecting the more hypoplastic partner and augmenting the better developed one (see Technique section).
- This technique is indicated when the dominant partner alone is sufficient to be a thumb with good appearance and function.
- It is the easiest and the most favored approach. It can be applied to all types of polydactyly and is the most common operation for types IV to VI.
- The main sequence of this procedure is as follows:
 - Disarticulation of the discarded partner but preservation of a ligamentoperiosteal flap and (if present) muscle insertion
 - Shaving of redundant proximal articulation
 - Osteotomies to correct angulation, if needed

- Reattachment of the ligamentoperiosteal flap and muscle insertions
- Rebalancing of eccentrically aligned extensor and flexor tendons, if needed

Sharing Technique

- The sharing technique uses parts from both partners to create a single digit. The most common expression of this technique is the Bilhaut operation, which removes central tissues and combines two digits into one.
- The procedure is indicated for nearly symmetrical but hypoplastic partners when removal of one partner only would leave a small thumb.
- The original Bilhaut technique removed equal parts from symmetrical partners but resulted in unsatisfactory outcomes including nail ridging, growth disturbance, and stiffness.
- The modified Bilhaut technique proposed by Baek⁴ shows more promising results. It removes extra-articular unequal parts from symmetrical partners, thus avoiding articular reconstruction and creating a well-contoured distal phalanx for the nail.
- The technique is typically performed for types II and III thumbs when the two partners are small but nearly equal in size.
- It can also be applied to type IV thumbs, but because the phalanges are usually asymmetrical, articular step-offs and bony misalignment are more likely to occur, resulting in less satisfactory outcomes.⁵
- Dorsal and volar incisions are made, the central soft tissue is excised, and the phalangeal components are identified. The dominant phalanx's articular surface is preserved. Similarly shaped extra-articular osteotomies are performed in each phalanx such that the defect in the dominant distal phalanx will be matched by a small nonarticular, soft tissue-bearing bone segment of the nondominant distal phalanx (**FIG 2**). The phalanges are then opposed and secured with Kirschner wires or sutures.

FIG 2 • In the modified Bilhaut operation for type II radial polydactyly, an extra-articular portion of each distal phalanx is shared to reconstruct one distal phalanx. Typically, a greater portion of the more dominant partner is preserved. Kirschner wires (shown) or sutures provide fixation for the osteotomy.

FIG 3 • In the original Bilhaut operation, half of each distal phalanx was used to reconstruct the thumb. **A.** The contour was suboptimal, leading to a groove in the nail. **B.** In the modified Bilhaut technique, slight volar axial rotation of the distal phalanges prior to fixation

ensures a smoother nail contour.

- Slight volar axial rotation of the distal phalanges prior to fixation will ensure a smoother nail contour without a groove, avoiding the so-called seagull deformity (**FIG 3**).
- The nail bed and skin are then repaired using fine sutures.

Acral Transposition

- On-top plasty is performed when one digit has better proximal components and the other has better distal components.
- This reconstruction is more common for cases with metacarpal or carpometacarpal arborization such as in types V to VII radial polydactyly.
- The procedure involves moving the better distal component of one partner onto the better proximal component of the other.
- The better distal component is isolated as a neurovascular island flap, and an osteotomy is performed at the desired level of transfer. The lesser distal component is excised and an osteotomy of the better proximal component is done at the desired level of transfer (**FIG 4**).
- The transfer is then performed and fixed with pins or interosseous wires. The intrinsic muscles are rebalanced and the skin is closed.
- Joint and bone deviations should be corrected (to the greatest extent possible) in the first operation with osteotomies and tendon rebalancing as needed. Subsequent repairs may be needed with growth.⁶
- In more proximal cases (eg, type V and VI), the surgeon should carefully consider the first web space. Because the ulnar partner is the one that is most commonly preserved and it is usually ulnarly deviated, the surgeon should perform maneuvers necessary to make sure that the first web space will be sufficiently wide.

Preoperative Planning

- Discuss risks, benefits, and expectations with parents on the day of surgery.
- Specifically outline the risks of scarring, joint deviations, stiffness, and bulges.

Positioning

- The patient is positioned supine with the arm out on a small hand table.

Approach

- Incisions are planned carefully prior to use of the tourniquet. The author prefers mid-lateral incisions to dorsal incisions, since they produce the best appearance.
- In infants and toddlers, an Esmarch bandage is used as a tourniquet.

FIG 4 • Acral transposition (“on-top plasty”) is usually indicated in more proximal radial polydactyly where one partner is dominant distally and the other is dominant proximally. **A.** In this case, the dominant ulnar distal partner will be transferred to the dominant proximal radial partner. Osteotomy sites are indicated in blue highlighting. The shaded portion of the ulnar partner’s metacarpal will be discarded. The skin incisions are planned such that plenty of skin is preserved on the hand from the radial partner. The goal is to dissect the ulnar partner as a vascularized island flap and translate it into the soft tissue sleeve of the radial partner. The wound where the ulnar partner resided will then be closed linearly, thus constructing a wide first web space. **B.** During the operation, the distal radial partner is discarded while any intrinsic muscles that attach to it are preserved for subsequent attachment onto the transferred partner. **C.** After the ulnar partner is isolated as a vascularized island flap, osteotomy is performed,

and it is transferred onto its new position and secured with interosseous wires or Kirschner wires. The intrinsic muscles are reattached, and the skin is closed, resulting in an improved web space.

TECHNIQUES

■ Reconstruction of Type IV Radial Polydactyly

Markings and Exposure

- The case of a 9-month-old boy with type IV polydactyly is presented with step-by-step surgical treatment (**TECH FIG 1A–C**).
- Draw the markings for a mid-lateral closure. Leave excess skin on the preserved partner and trim the skin later to create a custom closure (**TECH FIG 1D,E**).
 - The closure takes extra time but improves appearance.
- Once the tourniquet is applied, incise the dorsal markings and dissect sharply to the extensor tendon (**TECH FIG 1F**).
- Develop a plane above the extensor mechanism to just beyond the metacarpophalangeal (MP) joint (**TECH FIG 1G**).
- Incise the extensor tendon distal to its bifurcation and dissect under the extensor above the MP joint capsule.
- Incise the palmar markings; dissect and divide the neurovascular bundle (**TECH FIG 1H**).
- Dissect a plane over the flexor mechanism and the intrinsic abductor of the thumb (**TECH FIG 1I**). The abductor usually inserts on the radial and volar aspects of the proximal phalanx, but the anatomy is quite variable.

Flap Creation

- Design a proximally based periosteal flap on the radial aspect of the proximal phalanx (**TECH FIG 2A**).
- Incise the markings and elevate this flap with the radial partner's MP joint radial collateral ligament and the abductor muscle (**TECH FIG 2B**).
 - This flap will be used for subsequent reconstruction of the retained partner.

- Isolate and divide the extrinsic flexor tendon (**TECH FIG 2C**).

Disarticulation, Osteotomy, and Fixation

- Disarticulate at the MP joint. A bifid metacarpal head will now be visible (**TECH FIG 3A**).
- Cut the metacarpal head that articulated with the discarded partner (see **TECH FIG 2B**).

TECH FIG 1 • Type IV radial polydactyly in a 9-month-old boy. **A,B.** Anteroposterior clinical and radiographic views demonstrate a smaller, less developed radial partner. The ulnar partner is inline (parallel) to the metacarpal, and so an osteotomy of the metacarpal will not be needed. **C.** Simplified anatomy of radial

polydactyly. The abductor pollicis brevis muscle can have variable, and potentially multiple, insertion sites, such as onto the extensor, the bone, and the flexor tendon. If on-top plasty is planned, the insertion of the adductor pollicis should be considered. **D,E.** Dorsal and palmar views of the operative markings for planned excision of radial partner. A mid-lateral closure is planned. Excess skin is left on the retained partner for subsequent closure. **F.** The dorsal skin incision has been incised, the dorsal veins are cauterized, and a plane is developed over the extensor mechanism. **G.** The dorsal skin flap is elevated proximal to the MP joint. **H.** The volar incision is made, and the neurovascular bundle to the radial partner has been identified. **I.** The volar skin flap is elevated to expose the flexor tendon and the intrinsic abductor musculature.

- If only cartilage is involved (in minor cases), a knife will be sufficient to complete this task (**TECH FIG 3B**).
- In most cases, however, a retrograde osteotomy with a saw or a fine bone cutter is needed (**TECH FIG 3C**).
- Assess the need for closing wedge metacarpal osteotomy. When MP joint ulnar angulation of the retained partner is prominent, a closing wedge osteotomy is needed (**TECH FIG 3D**).
- Pin fixation is necessary after osteotomy (**TECH FIG 4**). Insert a retrograde 0.028 in. Kirschner wire from the ulnar side.

Tendon Correction in Type IV Polydactyly

- In divergent-convergent (rhomboid) type IV polydactyly, the extensor and flexor tendons can have eccentric insertions onto the distal phalanges (**TECH FIG 5**).

TECH FIG 2 • A. A proximally based periosteal flap is designed. The flap will include the radial collateral ligament and the abductor muscle insertion. Note that the muscle is inserting onto the bone (periosteum) and the flexor tendon. **B.** Technical maneuvers necessary for reconstruction of type IV radial polydactyly. The periosteal/muscle flap has been lifted, the dotted area showing the previous area of flap adherence. It is ideal to leave a long periosteal cuff on the flap to make subsequent repair easier. The radial head of the bifid metacarpal is cut, and a closing wedge osteotomy is performed if there is deviation of the ulnar partner. **C.** The flexor tendon is isolated. Note the periosteal/muscle flap reflected proximally and held with forceps.

TECH FIG 3 • **A.** The radial partner has been disarticulated at the MP joint, and the bifid metacarpal head is noted. **B.** In minor cases, such as this one, the radial head of the metacarpal is mostly cartilaginous and can be excised using a blade. **C.** In most cases, the radial head of the metacarpal has an osseous component and a retrograde osteotomy with a saw is needed. **D.** Illustration demonstrates result after closing wedge osteotomy (secured with a pin) and reattachment of the periosteal/muscle flap.

TECH FIG 4 • A,B. A different patient is demonstrated with type IV radial polydactyly and more significant ulnar angulation of the ulnar partner at the MP joint. Improvement in angulation is noted after closing wedge osteotomy and pin fixation intraoperatively **(C)** and 3.5 weeks postoperatively **(D)**.

TECH FIG 5 • In rhomboid type IV polydactyly, the extrinsic tendons can attach eccentrically on the distal phalanges, thus exaggerating the deviation. If these abnormal insertions are not addressed, deviation can recur with growth.

- If left alone, these abnormal tendons can contribute to long-term misalignment and deviation of the thumb.
- They should be detached and reattached at the proper location on the distal phalanx.

Reattachment and Closure

- Reattach using sutures the flap of periosteum, collateral ligament, and muscle to the radial aspect of the retained proximal phalanx (**TECH FIG 6A**).
- After removal of the radial metacarpal head, the radial aspect of the

remaining metacarpal is bare and not attached to the collateral ligament; however, the collateral ligament heals well to the metacarpal.

- Additional reinforcing sutures to the metacarpal may be necessary.
- There will be excess skin in multiple dimensions. In most cases, the excess skin can be trimmed and “cheated in” and a mid-lateral closure completed.
- If there is abundant excess, a better approach is to make a separate palmar incision along the MP joint flexion crease to excise skin in an orthogonal dimension (**TECH FIG 6B,C**).
- Apply a soft dressing and a long-arm cast for 3 to 4 weeks.

TECH FIG 6 • **A.** The periosteal, collateral ligament, and muscle flap have been reattached to the proximal phalanx with additional reinforcing sutures onto the radial aspect of the metacarpal. **B.** Final appearance after closure. **C.** Note that the “dog ear” has been ablated via a separate incision in the volar MP joint flexion crease.

PEARLS AND PITFALLS

Surgical management

- It is the author’s opinion that, when possible and especially in more proximal polydactyly cases, resection and reconstruction give a

better aesthetic outcome than does the Bilhaut “sharing” technique. The downside is that the thumb is usually smaller.

- The surgeon should have a well-defined stepwise approach for each case.

Technique

- When developing muscle and/or collateral ligament flaps, leave a long periosteal sleeve to allow easier subsequent reattachment.
- In polydactyly cases that have multiple levels of joint deviation (eg, rhomboid type IV), multiple simultaneous osteotomies should be undertaken.

POSTOPERATIVE CARE

- Immobilize the extremity with a long-arm cast with the elbow at 90 degrees of flexion for 3 or 4 weeks. The author immobilizes longer in those patients who have undergone osteotomies.
- Remove the cast (and pins) and refer to hand therapy for fabrication of a thermoplast thumb spica splint.
- Start range-of-motion exercises.
- Wear the splint for 2 or 3 weeks at night.
- See patients once every 1 to 2 years to assess function, growth, and joint deviation.

OUTCOMES

- Although multiple different outcome scoring systems have been proposed, reliability appears highest for the scoring system proposed by the Japanese Society for Surgery of the Hand.⁷
- The results after polydactyly repair are generally satisfactory but depend greatly on the initial deformity.
 - Results of type III, V, and VI repairs are less satisfactory.
- The affected side is weaker than the normal side and revisions are common, but patients have favorable scores on objective outcome measures.⁶
- Long-term unfavorable outcomes after repair include deviations and angulations (with associated pain), bony prominences, stiffness, and nail deformity. Deviations maybe the result of trapezoidal or delta phalanges, canted or unstable joints, or asymmetrical growth and can occur long term despite an adequate initial repair.
- The Bilhaut procedure has had unfavorable results including stiffness and nail deformity. Many prefer resection and reconstruction to this technique,⁵

although the aforementioned modification of the Bilhaut technique for more distal polydactyly cases⁴ has shown promising results and gained support.

COMPLICATIONS

- Immediate complications are rare and include bleeding, infection, and wound dehiscence.
- Wound dehiscence is almost always due to inadequate immobilization and can be prevented with a long-arm cast.

66 Index Finger Pollicization for Hypoplastic Thumb

CHAPTER

Amir H. Taghinia, Brian I. Labow, and Joseph Upton

DEFINITION

- The thumb is the functional keystone of the hand. The basic hand unit has three main elements: a thumb, a web space, and a prehensile post. Severe hypoplasia or aplasia of the thumb leads to significant functional impairment.
- Index finger pollicization is the procedure of transposing the index finger into the position of the thumb. It is the quintessential operation of hand surgery, incorporating key principles and requiring meticulous technique and execution.
- The methods outlined herein include further refinements¹ to the techniques initially proposed, developed, and refined by D. Buck-Gramcko² and J. W. Littler.³

ANATOMY

- The normal thumb is perfectly adapted for pinch and grasp. It is broad with osseous and articular structures that move in multiple planes. Its intrinsic muscles provide a short moment arm, powering the movement enabled by the osseoarticular column.
- The normal first web space has a gentle curve spanning from the thumb metacarpophalangeal (MP) joint to the index finger MP joint.
- A thumb is considered hypoplastic if any of its osseous, musculotendinous, or articular components is deficient or if the web space that it forms with the index finger is shallow.
- The modified Blauth⁴ classification system provides a surgically useful basis for categorizing thumb hypoplasia. Most surgeons agree that Blauth types I, II, and IIIA thumbs can be reconstructed, whereas Blauth types IIIB, IV (*pouce flottant*), and V (aplasia) hypoplastic thumbs require index finger pollicization.

- The differentiating factor between Blauth type IIIA and IIIB thumbs is the presence (IIIA) or absence (IIIB) of a functional carpometacarpal (CMC) joint.
- The preoperative state of the index finger is the greatest determinant of long-term postoperative function after pollicization.^{1,5} Patients with normal index fingers will have the best function. Abnormal index fingers are typically seen in patients with radial longitudinal deficiency. Abnormalities include stiffness, joint hypoplasia, incomplete intrinsic muscles and/or extrinsic tendons, and hypoplastic or anomalous vessels and nerves.

PATHOGENESIS AND NATURAL HISTORY

- Thumb hypoplasia occurs as a result of multiple potential factors, including genetic (associated syndromes), environmental, teratogenic (thalidomide), and idiopathic causes.
- It is considered to be a malformation, based on the Oberg, Manske, and Tonkin classification of 2010.⁶
- Thumb hypoplasia occurs in 1 out of 100 000 live births.
- A large number of patients with thumb hypoplasia have associated conditions such as cardiac or hematologic anomalies.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients are usually seen in infancy. In severe cases such as type IV or type V, the diagnosis is clear. Nevertheless, the difference between type IIIA and IIIB can be difficult to ascertain in a newborn. The integrity of the CMC joint is sometimes not obvious on plain film radiographs. Functional differentiation can be made by allowing the child to grow and watching the toddler at play—if the thumb is not used, the joint is likely nonfunctional.
- Indeed, most children with severe thumb hypoplasia will scissor pinch using the index and middle fingers in lieu of the nonfunctional thumb. With time, the web space between the index and middle fingers widens and the index finger starts to pronate. These patients are ideal candidates for pollicization.
- The hand surgeon should be aware of the conditions associated with thumb hypoplasia, and have a low threshold to refer if suspicions arise.
 - In particular, roughly 50% of patients with Fanconi anemia (an inherited defect in DNA repair leading to bone marrow failure and premature malignancy) manifest thumb hypoplasia, along with a variety of other anomalies. The diagnosis of Fanconi anemia can be made via a blood test early in life.

- Other associated conditions include Holt-Oram syndrome, VACTERL association, radial longitudinal deficiency, and thrombocytopenia-absent radius (TAR).

IMAGING

- Plain radiographs help to determine the status of the CMC joint, any abnormalities of the index finger, and the status of the distal radius and ulna (presence of radial longitudinal deficiency).
- The authors do not routinely perform angiography.

DIFFERENTIAL DIAGNOSIS

- Differentiate type IIIA and IIIB thumbs by functional assessment of the child.

SURGICAL MANAGEMENT

- The authors perform index finger pollicization in toddlers around 2 years of age, but the timing is more dependent on size, weight, and other medical comorbidities that may delay intervention.
- The procedure is technically easier if performed in a toddler, rather than an infant.
- Manske⁵ has shown that pollicization can be functional and effective even if performed later in childhood.
- The main objective of the operation is to shorten and reposition the index finger into a recessed, pronated, and palmarly abducted position, as well as to simultaneously create a well-contoured web space.
- The main steps of the procedure are as follows:
 - Make incisions in a modified Y to V fashion that will allow the index finger to be recessed and rotated.
 - Isolate the index finger as a neurovascular island.
 - Disinsert and isolate the intrinsic muscles of the index finger.
 - Excise the metacarpal, ablate the metacarpal growth plate, and secure the metacarpal head in a hyperextended position into the cut metacarpal base.
 - Rebalance the extensor tendons.
 - Rebalance the intrinsic muscles.
 - Adjust skin flaps to create an aesthetically pleasing outcome.
- Almost always, there is sufficient skin to transpose the index finger and close all the wounds without needing skin grafts.
- Any open wounds or flaps under tension are the result of poor incision

planning or execution.

- Simultaneous bilateral index finger pollicization is not performed.

Preoperative Planning

- Again discuss risks, benefits, and expectations with parents on the day of surgery.
 - Specifically outline the risks of flap loss (partial or complete), ischemia of the digit, poor positioning, and suboptimal function and the potential need for revisional or adjunct procedures later in childhood.
- The surgeon needs fine surgical instruments and vessel loops for tagging and dissection of important structures.

Positioning

- The patient is positioned supine with the arm out on a small hand table.

Approach

- Incisions are planned carefully prior to use of the tourniquet. Dorsal and palmar approaches are needed.

TECHNIQUES

■ Index Finger Pollicization

Markings and Dissection

- Place two small round marks, one at the base of the index finger and the other at the position where the new thumb base will be placed. Mark a racquet-shaped incision around the base of the index finger. Extend these markings onto the proposed new thenar flexion crease; this will be the recession incision.
 - The markings for the incisions should be planned so they extend through the round marks (**TECH FIG 1A, B**).
 - The back-cut incision is not made until the ray has been transposed.
- Exsanguinate the upper extremity and inflate a tourniquet in the upper arm.
- Incise transversely on the dorsum of the index finger (**TECH FIG 1C**). (Note that the patient shown in the clinical photographs has radial

longitudinal deficiency and a stiff index finger.)

TECH FIG 1 • A,B. Dorsal and palmar markings. A racquet-shaped incision is planned around the index finger. The index finger will be recessed into the proposed thenar flexion crease incision. **C.** Dorsal incision is made, and veins are identified and dissected. One sizeable vein should be present on either side of the extensor tendon. **D.** The palmar incision is made and a flap raised on the palmar

fascia. The flap is reflected and tacked back for the remainder of the case. **E.** The ulnar contribution of the common digital artery to the index-middle web is isolated (on the green background). The ulnar digital nerve of the index finger is visualized (*arrow*). **F.** The A1 pulley is exposed and ready to be divided. The scissor tip is underneath the pulley. **G.** The fine-tipped clamp is underneath the intermetacarpal ligament. The retractor is pulling the lumbrical muscle to the middle finger. The artery and nerve are free with the index finger. **H.** First dorsal and volar interosseous muscles. These muscles will be rebalanced to mimic the intrinsic muscles of the new thumb.

- Upward traction on the skin will reveal the longitudinally oriented veins on either side of the extensor tendon at the MP joint level. These veins run in the plane between the superficial (small globular) fat and the deep (large lobular) fat.
 - Dissect these veins proximally beyond the mid-dorsum of the hand.
 - Place blue vessel loops around these veins to help with dissection and subsequent identification.
- Incise the remaining volar markings and raise a volar skin flap just above the palmar fascia up to the middle finger (**TECH FIG 1D**).
- Identify and dissect the neurovascular bundle in the index-middle web, and isolate the middle finger contribution of the common digital artery (**TECH FIG 1E**). Ligate this branch.
- Separate the nerves. Intraneural loops may be present and should be carefully dissected.
- Divide the A1 pulley (**TECH FIG 1F**).
- Isolate the intermetacarpal ligament and divide it sharply (**TECH FIG 1G**).
- Dissect and isolate the intrinsic muscles of the index finger—the first dorsal interosseous and the first volar interosseous (**TECH FIG 1H**).
 - The first dorsal interosseous may have two heads; each should be isolated. A small lumbrical may also be present.
- Dissect and isolate the extensor tendons.

Metacarpal Preparation and Osteosynthesis

- Incise and strip the periosteum off the diaphysis of the metacarpal.
- Cut the metacarpal head at the level of the growth plate (**TECH FIG 2A**). This can usually be done with a blade.
- Cut the metacarpal base in a volar oblique fashion using a saw. The angle of this cut determines the degree of palmar abduction of the neothumb. Ideal is about 60 degrees of palmar abduction.
- Measure the length of the removed metacarpal (**TECH FIG 2B**). This measurement approximates the length of extensor to shorten.
- Ablate the growth plate using a blade (**TECH FIG 2C**). Avoid injuring the collateral ligaments.
- Affix the metacarpal head to the metacarpal base (**TECH FIG 2D**).

TECH FIG 2 • A. The metacarpal head is divided. The metacarpal has been stripped of its periosteum. The first dorsal interosseous muscle is seen retracted with a black suture at its insertion. A volar oblique

osteotomy is planned at the base of the metacarpal (*purple* markings). **B.** The removed metacarpal. Figure left is distal; figure top is dorsal. The length of the excised bone approximates the shortening of the extensor tendons. **C.** Use a blade to ablate the metacarpal physis. **D.** The metacarpal head should be placed at its base with the joint in hyperextension. The angle of the base osteotomy determines the degree of palmar abduction. **E.** Suture osteosynthesis gives more control for accurate positioning of the metacarpal head. The base is outlined in white.

- The metacarpal head should be pronated and flexed so its cut surface aligns with the cut surface of the base. The MP joint should be hyperextended.
- If placed in a neutral or flexed position, the MP joint will hyperextend naturally with time. Placing it initially in hyperextension prevents this problem.
- Place a braided nonabsorbable, double-armed suture (3-0 Ethibond) in a mattress fashion into the metacarpal head (**TECH FIG 2E**). Insert the needles from inside the cut surface of the metacarpal base dorsally and tie. Additional sutures to the nearby soft tissues help to secure the fixation. Wires are not needed.

Dorsal Flap Placement

- Make the back-cut incision. Advance the dorsal hand skin flap and assess a position on the digit where the dorsal flap will inset (**TECH FIG 3A**).
- Design a straight, longitudinal incision on the dorsum of the transposed digit. The incision typically stops just proximal to the PIP joint. Incise the skin and spread down to the extensor tendon to separate the veins and subcutaneous tissue (**TECH FIG 3B**).
- Dissect the lateral bands from the extensor mechanism for subsequent attachment to the intrinsic muscles on each side of the new thumb (**TECH FIG 3C**).
- Release the tourniquet and watch for vascularity of the fingertip (**TECH FIG 3D**).

Tendon Repair

- Rebalance the extensor tendons. Dissect and separate the extensor indicis proprius (EIP) from the extensor digitorum communis (EDC). On occasion, the interval between these two tendons can be difficult to ascertain.

TECH FIG 3 • A. Once the osteosynthesis is complete, the dorsal flap is advanced and the location of the cut back incision on the index finger is determined. **B.** An incision is then made, and the veins and subcutaneous structures are separated. **C.** The lateral bands on either side of the extensor are delineated. **D.** Releasing the tourniquet allows one to assess vascularity of the digit. Furthermore, any

bleeding sites can be addressed at this time.

TECH FIG 4 • A. The EIP is shortened and secured with a side-to-side tenorrhaphy. The EDC is shortened and attached to the ulnar base of the proximal phalanx. **B.** The first dorsal interosseous and volar interosseous are sutured to the lateral bands. If the first dorsal interosseous has two heads, one head can be directly attached to the periosteum on the radial side of the middle phalanx.

- Shorten the EIP by approximately the length of bone removed. Side-to-side tenorrhaphy works well (**TECH FIG 4A**). The digit should hold an extended posture. The EIP becomes the new extensor pollicis longus.
- Disconnect the EDC, shorten it, and reattach it to the ulnar base of the index finger proximal phalanx (see **TECH FIG 4A**). Attaching it to the ulnar base of the proximal phalanx enhances pronation. The EDC becomes the new abductor pollicis longus.
- Reattach the first dorsal interosseous to the radial lateral band and the first volar interosseous to the ulnar lateral band (**TECH FIG 4B**). The first dorsal interosseous will mimic the abductor pollicis brevis, and the first volar interosseous will mimic the adductor pollicis muscle.
- If the first dorsal interosseous has two heads, one head can be attached to the periosteum of the radial middle phalanx. The digit should hold an extended posture but be easily flexed down with gentle finger pressure.

Completion

- Inset the proximal neothumb skin flap into the proximal corner of the thenar crease incision.
- Close the web space with 6-0 chromic sutures.
- Inset the remaining skin flaps and close (**TECH FIG 5**).
- Apply antibiotic-impregnated gauze to all incisions and cover with sterile gauze.
- Wrap loosely and apply a well-padded long-arm cast. Keep the tip of the neothumb exposed for vascular checks postoperatively.

TECH FIG 5 • A–C. The final outcome after inseting of the skin and closure of the web space. (As mentioned previously, this patient had radial longitudinal deficiency.)

PEARLS AND PITFALLS

Physical findings

- It may be difficult to differentiate between type IIIA and IIIB thumbs in an infant. Allow the child to grow. With time, the functional differentiation becomes more apparent.

Technique

- The more common, and more difficult, vascular problem that occurs is venous insufficiency. Be most cautious with the veins

	during the initial dissection. Although it may oppose common practice, using a blade (instead of scissors) to sharply lift the dorsal skin flap off the veins works well at avoiding venous injury. ■ Neural loops around the arteries can be difficult to separate especially in smaller children. Do not hesitate to employ a microscope or microinstruments for this purpose. ■ Obtain careful hemostasis and close the skin while the tourniquet is down so hematoma is avoided.
Postoperative	■ Because the flexor tendon is not routinely shortened, it takes up to 6 months for digit to start actively flexing.
Therapy	■ Early on, a few children will avoid use of the new thumb and instead start pinching with the middle and ring fingers. To discourage this behavior, consider buddy taping the middle and ring fingers together.

POSTOPERATIVE CARE

- Remove the cast after 3 to 4 weeks of immobilization.
- Fashion a thumb spica thermoplast splint that can be worn for 2 to 3 weeks at night for protection.
- Start range-of-motion exercises with hand therapy.

OUTCOMES

- Functional outcomes of pollicization depend mostly on the preoperative status of the index finger. Those patients with normal index fingers will have the best results, whereas those with stiff or abnormal index finger (eg, radial longitudinal deficiency) will have suboptimal results.^{1,5}
- The new thumb is a suboptimal replica of a normal thumb. It lacks the broadness, strength, and osteoarticular integrity of a normal thumb. Under the best of circumstances, one can expect about 50% pinch strength as compared to an unaffected contralateral side.

COMPLICATIONS

- Positional problems include the new thumb being too long or not adequately pronated and/or abducted. Both of these complications make the thumb appear like a shortened finger, the former because it is too long and the latter because it is in the same plane as the fingers.
- Inadequate web space is mainly a problem of poor incision planning or excessively thinned/ischemic flaps.

- Hematoma is most commonly seen on the dorsum where it can cause ischemia of the dorsal skin (via pressure and direct toxicity) or of the new thumb (via pressure on the draining veins).
- Vascular insufficiency is a dreaded complication and can be arterial or venous in origin. Fortunately, these complications are rare.
 - Arterial insufficiency is less commonly due to kinking and compression and more commonly due to direct injury. Once the injury is recognized, it should be promptly repaired using the operating microscope.
 - Venous insufficiency can be due to direct injury, kinking, or compression. Ensure that veins are adequately dissected proximally, that they lie tension-free without kinking, and that there is no hematoma or site of compression.
- Opposition weakness is commonly seen in the long term. Opponensplasty with abductor digiti minimi transfer (Huber) can provide additional power. If needed, this procedure is performed several years after the pollicization.

67 Second Toe-to-Thumb Transfer for Hypoplastic Thumb

CHAPTER

Amir H. Taghinia, Brian I. Labow, and Joseph Upton

DEFINITION

- Toe-to-thumb transfer for congenital conditions is usually indicated in cases in which the carpometacarpal joint and (at least) the proximal part of the metacarpal are intact and functional but the remainder of the thumb is absent or diseased.¹
- Either the great toe or the second toe is typically used for thumb reconstruction. Although the modified great toe looks more like a thumb, the length of first metatarsal that can be harvested without functional loss in the foot is quite limited.
- In congenital patients,² toe-to-thumb transfer is most commonly performed for amniotic constriction bands, symbrachydactyly (atypical cleft hand), transverse failure of formation, (typical) cleft hand, and highly select cases of type IIIB thumb hypoplasia.
- The congenital conditions in which the thumb is diseased include macrodactyly and vascular anomalies.

ANATOMY

- The second toe is smaller than the normal thumb. It has a lower width to pulp depth ratio, thus appearing more clubbed and bulbous. It has three phalanges and a metatarsophalangeal joint, which, in the foot, functions as a hyperextension joint rather than a flexion joint as in the thumb.
- The arterial anatomy of the second toe can be variable. The dorsalis pedis artery is the main proximal blood supply. It gives rise to the first dorsal metatarsal artery (FDMA) and the first plantar metatarsal artery (FPMA) via

anastomosis with the medial plantar artery, a branch of the posterior tibial arterial system of the foot.

- There are three common branching patterns (**FIG 1**)³:
 - The FDMA lies superficial to the first dorsal interosseous muscle.
 - The FDMA lies within or deep to the first dorsal interosseous muscle.
 - The FDMA is diminutive or absent.
- The more plantar the dominant system, the more difficult is the dissection.
- The venous anatomy provides abundant large veins. Venous branches of the second toe reside in the dorsal subcutaneous plane; a vein on either side of the toe drains to the lesser saphenous (lateral) or great saphenous (medial) veins.
- The second toe has two extensor tendons—extensor digitorum longus and brevis—and two flexor tendons—flexor digitorum longus and brevis. The extensors approach the second ray in an oblique fashion, from lateral to medial. Two plantar digital nerves travel below the transverse metatarsal ligament and arrive on either side of the toe to provide sensation to the pulp.
- Unlike the first ray of the foot where the metatarsal is crucial for gait, the second ray's metatarsal is expendable and its entire length may be harvested if needed. The goal should be to construct a new thumb of normal length. In full adduction, a normal thumb extends to the proximal interphalangeal (PIP) joint of the adjacent index finger.
- In congenital conditions where the foot is also affected, the surgeon may carefully consider harvesting an anatomically abnormal toe. Investigation of arterial anatomy under these special circumstances is, at a minimum, important to avoid vascular compromise of the toe transfer—or worse, the other toes.
- In cases of amniotic constriction bands, the proximal anatomy of the hand is usually normal. However, in other conditions such as symbrachydactyly or transverse failure, the anatomy of the hand may not be normal.

FIG 1 • Variations in arterial anatomy of the first web

space of the foot. As it reaches the base of the first and second metatarsals, the dorsalis pedis artery can continue on dorsally as the first dorsal metatarsal artery (FDMA) and send a plantar branch, the first plantar metatarsal artery (FPMA). **A.** The FDMA may be the dominant blood supply to the second toe and may lie superficially to the first dorsal interosseous. **B.** Alternatively, the FDMA may lie within or deep to the first dorsal interosseous. **C.** Last, the FDMA may be diminutive or completely absent.

FIG 2 • This 3-year-old patient with typical cleft hand/cleft foot syndrome (the example case throughout) has two ulnar fingers but no thumb (**A**), as well as webbed great and second toes (**B**).

- Variations in anatomy tend to be the rule and include deficient or missing tendons, nerves, muscles, and arteries. These variations may only become evident during the operation, and so the surgeon should be prepared with

multiple contingency plans. Angiography is used more liberally in these patients.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A full history and physical examination should be obtained to define and document deficient anatomy, assess current functional use, ascertain associated conditions, and set goals for reconstruction.
- Physical examination of the hand (**FIG 2A**)
 - The skin is inspected for suppleness, turgor, and pliability.
 - The soft tissue around the thumb is inspected for presence of intrinsic muscles.
 - Dimples in the skin may indicate underlying tendons.
 - Pulse examination and an Allen test are necessary to assess the blood supply to the hand and presence of palmar arch.
- Physical examination of the foot (**FIG 2B**)
 - General appearance of the foot and/or toe may indicate presence of any anatomic abnormalities. In amniotic constriction bands, the toes may also be affected.
 - Pulses are examined. A pencil Doppler probe can be used to ascertain the presence of an FDMA by tracing its course on the dorsum of the foot.

IMAGING

- Plain radiographs of the hand and foot are required (**FIG 3**).
- Routine angiography is debatable; nevertheless, it is the authors' practice to obtain angiography of the hand and foot on most patients (**FIG 4**).
 - Angiography helps to create a road map and a plan for the operation. Questions such as the need for vein grafting (foot), end-to-side vs end-to-end anastomoses (hand), and residual vascularity of the foot after flap harvest can be answered preoperatively. This planning is essential in cases where a team approach with multiple surgeons is undertaken. Certainly for patients with abnormal foot anatomy (**FIG 5**), angiography helps with preoperative planning to ensure a viable flap.

FIG 3 • Radiography of the example case shows three metacarpals on the radial side of the hand (**A**) and separate skeletal structures in the foot despite webbing of the great and second toes (**B**). Note that there are only two phalanges in the second toe. The epiphysis of the second metatarsal is not present in this early radiograph, but it is distally located in subsequent films (see **TECH FIG 7A**), indicating that this is indeed a phylogenetic second toe rather than a preaxial synpolydactyly.

SURGICAL MANAGEMENT

- The time to perform the toe transfer should not be an arbitrary age but rather tailored to the individual child.
- Although it is important to perform the transfer as early as possible to take advantage of brain plasticity and enhanced nerve regeneration, the child has to be of appropriate size to allow a technically feasible operation.

FIG 4 • Angiographic variation in arterial anatomy of the foot (FDMA indicated by *white arrow*). The variations outlined in **FIG 1** are seen in the angiograms, with a large, dominant FDMA (**A**); a thinner, intramuscular FDMA (**B**); a diminutive FDMA (**C**); and no FDMA (**D**). The plantar system is dominant in **B** to **D**.

- Specifically, the vessels tend to be too small for a predictable operation in most children under the age of 2.
- The decision-making process for the parents (and the child) often requires substantial discussion. The sacrifice of part of a foot for improved function of the hand can be a difficult decision, especially when there is a small risk that the toe may not survive or that the function may not be optimal.
- Thorough preparation of the parents for this process, including an honest explanation of the risks and expected outcomes, is a crucial preoperative step.
- Radiographs, preoperative and postoperative photographs, molds, and movies of other patients can help with the decision-making.
- Jones advocates arranging for parents to meet the families of previous patients with toe transfers.¹
- Multiple toe transfers are possible and can be performed reliably. Reconstruction of a thumb and finger(s) usually requires separate toes from both feet.
- In contrast, multiple toes from the same foot can be used to reconstruct fingers.
- Preparation of the hand recipient site with the addition of skin and soft tissue as a first-stage procedure is rarely needed in congenital cases.
- However, in cases in which there is a paucity of soft tissue and skin (eg, where the base of the thumb is very short), transfer of skin via pedicled (eg,

groin or lower abdomen) or free (eg, anterolateral thigh) should be considered at least 6 to 9 months before definitive toe transfer.

- Skin grafting is often necessary and is much better tolerated on the hand than on the foot.

Preoperative Planning

- Simultaneous dissection of the donor toe and the recipient site requires two surgical teams. This approach minimizes time of surgery and anesthesia and ensures that the critical portions of the operation take place during times when operating room staffing is optimal.
- A careful analysis of deficient length is critical to ensure optimal function in the future. Plan the length of the thumb needed and the appropriate length of the second ray to harvest to achieve this length.
- The surgeon will need fine instruments for toe and hand dissections, loupe magnification, microsurgical instruments, a microscope, a handheld Doppler probe, and an adhesive-backed, disposable finger pulse oximetry monitor for postoperative monitoring of the toe transfer. In addition, automatic clip appliers and vascular loops greatly enhance the dissection.

FIG 5 • Angiography of the foot of example case reveals

an FDMA deep to the first dorsal interosseous supplying a single diminutive common dorsal and a single large common plantar artery. The dominant (plantar) vessel to the tibial, webbed toes lies in the web space and extends distally to the tips, sending branches along the way to both toes **(A)** anteroposterior view, **(B)** lateral view. The entire vessel was harvested with the second toe.

Positioning

- The patient is positioned supine with the arm out on a small hand table. A small gel roll under the ipsilateral hip can help orient the foot into a more pronated position for dissecting the toe. The lower abdominal area for the skin graft is squared off with Steri-Drapes.
- Incisions are planned carefully prior to use of the tourniquet.

TECHNIQUES

■ Second Toe Flap

Markings and Incision

- Identify and mark the path of the dorsalis pedis and FDMA, if present, using a handheld Doppler probe.
- Squeeze the ankle and milk the soft tissue distally to allow the dorsal foot veins to engorge. Mark these veins.
- Draw a wedge-shaped incision around the second toe (**TECH FIG 1A,B**).
 - In the case of abnormal foot anatomy, the incisions will need to be modified (**TECH FIG 1C,D**).
- Exsanguinate the extremity and inflate a mid-thigh tourniquet.
- Incise the dorsal markings and extend the incision along the path of the FDMA.

Soft Tissue Dissection

- Identify, dissect, and follow the superficial veins to the large dominant veins.

Clip and divide all tributaries. Place blue vessel loops around the dominant veins and free them proximally.

- Identify and tag any dorsal sensory branches of the superficial peroneal nerve coursing to the second toe.
- Identify and dissect the extensor digitorum communis (EDC) tendon until enough length is achieved; transect it.
- Identify the short extensor tendon, which has a distal muscle belly and a thin tendon. Divide the tendon.
- Dissect proximal to the first and second metatarsal bases and identify the vascular pedicle. Place loops around the dorsalis pedis artery and its venae comitantes (**TECH FIG 2A**).
 - Usually, two comitant veins are present, but only one is suitable for microvascular anastomosis.
- Trace the pedicle distally to the FDMA, if present. The FDMA may lie dorsal to the first dorsal interosseous, may lie within or deep to the first dorsal interosseous, or may be absent (see **FIG 1**).
- Incise the first and second web space and plantar markings and dissect the soft tissues.
- Splay the great and third toes with a Gelpi retractor. This maneuver provides ample retraction and allows great visualization of the web space (**TECH FIG 2B**).
- Identify the neurovascular bundle on the fibular side of the great toe and the tibial side of the second toe in the first web space. Clip and divide the fibular digital artery to the great toe and sweep the vessels in the fibular direction (**TECH FIG 2C**). Similarly, clip and divide the tibial digital artery to the third toe, if present.

TECH FIG 1 • A,B. Typical incision placement for second toe flap on a normal foot. The Xs mark location of audible Doppler pulses. Minimal skin is taken with the toe to allow tension-free linear closure of the foot. **C,D.** Modified incision planning for abnormal foot anatomy seen in the example case. Straight-line dorsal and plantar incisions were planned distally, with a racquet-type diversion proximally on the plantar surface. The Xs mark the path of the (deep)

FDMA and (diminutive) dorsal common digital artery.

TECH FIG 2 • A. A dorsal superficial vein (*blue loop*) and the dorsalis pedis and its venae comitantes (*red loop*) have been identified and tagged. The muscle next to the artery, the extensor hallucis brevis, has been divided to expose the underlying vessels. **B.** Typical second toe dissection, dorsal view. Gelpi retractors help with exposure. A dorsal dominant arterial system is shown. The extensors to the second toe take an oblique course medially. The extensor hallucis brevis muscle (next to the artery) has been divided. **C.** The first web space has been exposed. The dominant, plantar common digital artery is shown with a clip on the great toe branch that has been divided. The entire common digital artery was kept with the second toe.

- Follow the artery proximal. The FDMA may have a communicating branch to the FPMA that passes anterior to the intermetatarsal ligament (see **FIG 1**).
- Isolate and divide the intermetatarsal ligament.

Artery and Nerve Dissection

- At this point, the plantar and dorsal systems are outlined and the dominance of the arterial system should be clear, even if an angiogram was not obtained.
- Select the dominant arterial system, and divide communicating branches as needed. The first dorsal interosseous may need to be divided; there are many small branches from the main pedicle to the bone and the muscle in this area.
- If the dominant system is plantar, the surgeon can avoid performing the tedious plantar dissection by using a vein graft to bridge the gap. The authors' practice, however, is to perform the full plantar dissection and avoid vein grafting.
 - Early osteotomy and elevation of the second metatarsal will help with exposure if the system is plantar dominant.
- Trace the artery all the way to the dorsalis pedis system. There is a hub of multiple arterial and venous branches at the base of the first and second metatarsals. Substantial additional length on the pedicle can be obtained if these branches are divided, and the dorsalis pedis system proper is used as the feeding vessel to the toe.
- Dissect the fibular and tibial digital nerves of the second toe to the common digital nerves in the respective proximal web spaces. These nerves are short and additional length is always necessary (**TECH FIG 3**).
 - Use microinstruments to gently tease the nerves to the second toe from the common digital nerve on both sides. Perform the intraneural dissection as far proximal as needed.
- Transect the digital nerves and mark them with either small clips or sutures.
- Identify the flexor digitorum longus and brevis tendons (see **TECH FIG 3**); dissect and divide these as far proximally as possible.

TECH FIG 3 • Typical second toe dissection, web space view. A dorsal dominant system is shown with the dorsal digital branch to the great toe clipped and divided. The proper digital nerves usually require intraneural dissection to obtain adequate length. The flexor system to the second toe should be divided as far proximal as possible.

TECH FIG 4 • The second toe has been fully dissected and remains attached to the foot via its blood supply, the dorsalis pedis (DP) and two superficial veins (V). The extensor digitorum longus (EDL) and brevis (EDB), the flexor digitorum longus (FDL) and brevis, and the tibial (DN^T) and fibular (DN^F) are outlined. The FDMA was deep to the first DI in this case.

Metatarsal Osteotomy and Flap Placement

- Incise the periosteum over the second metatarsal, retract the vessels and tendons dorsally, and cut the metatarsal at the preplanned location.
 - Even though there is temptation to leave redundant bone length on the flap, trimming the bone when the flap is free and all the structures are loose is tedious and can be dangerous. It is best to get the ballpark length right the first time and make only small adjustments during the transfer.
- Isolate the flap as a vascularized island (**TECH FIG 4**) and release the tourniquet.
 - Apply papaverine to the vessels and warm saline-soaked sponges to the wounds.
 - Assess the perfusion to the flap. If a difficult plantar system is encountered,

the dissection may require a second, albeit shorter, tourniquet run.

Closure

- Close the foot wound by suturing the intermetacarpal ligaments attached to the first and third metatarsals, thus closing the gap in the first web space.
- Close the skin wound using absorbable sutures.
- A skin graft may be used if needed, but it is imperative to avoid skin grafts on the plantar surface. A thin drain may be used for a few days (**TECH FIG 5**).
- Apply a well-padded leg cast.

TECH FIG 5 • Foot closure is complete. The fibular side of the great toe has been covered with a full-thickness skin graft.

■ Preparation of the Hand for Toe Transfer

- The steps for the hand are dependent on the given anatomy.
- Placement of the incisions is likely to differ for each case (**TECH FIG 6A**).
 - If the incisions for inset are distant from appropriate vessels (most cases), a separate dorsal/radial transverse wrist incision provides ample access to large dorsal veins and the dorsal branch of the radial artery in the anatomic snuffbox.
- Exsanguinate the arm and inflate a tourniquet.

- Make the incisions and raise flaps.
- Identify and tag two large dorsal veins and the dorsal branch of the radial artery. The authors prefer to use at least two veins for microanastomosis.
- Dissect, isolate, and tag the intrinsic muscles of the proposed new thumb.
- Identify the extrinsic extensor and flexor tendons. Multiple tendons may be present, in which case the best flexor and extensor should be chosen (**TECH FIG 6B**).
- Dissect, isolate, and tag the digital nerves.
- Prepare the bone for osteosynthesis. Options include Kirschner wires, 90-90 interosseous wiring, or plate and screws for fixation.

TECH FIG 6 • A. Markings for hand dissection. An ulnarly based skin flap is planned to partially cover the tibial portion of the second toe flap. A volar wrist incision exposes the radial artery. A dorsal transverse wrist incision exposes large dorsal veins. **B.** Recipient hand has been prepared. Of the three radial metacarpals, the middle one has been preserved for osteosynthesis while the other two adjacent ones have been removed. Long extensor and flexor tendons are retracted (*yellow loops*). The intrinsic muscles of the thumb base are reflected (*black sutures*).

■ Transfer of Toe to Hand

- Assess the length of the toe on the new thumb, and adjust the size by cutting the bone with a saw.
 - The fully adducted, normal thumb tip extends to the level of the index finger PIP joint.
- Perform the osteosynthesis of choice (**TECH FIG 7A**).
- The positioning of the thumb is critical for function. The CMC joint and the proximal metacarpal are already set; however, the surgeon does have control over the degree of pronation and radial/ulnar angulation of the new thumb. Ensure that the new thumb rests in an appropriate position of function.
- Gauge the tension on the flexor and extensor tendons. Balance these so that the toe rests in near full MP joint extension and minimal flexion of the toe PIP and DIP joints. Repair the extensor tendon and then the flexor tendon using side-to-side tenorrhaphies.
- Perform the arterial and venous anastomoses using an operating microscope and microinstruments. Ideally, an end-to-side arterial anastomosis is performed to the radial artery to avoid compromise of the palmar arch (**TECH FIG 7B**).
- Perform the neurorrhaphies using the microscope; these repairs can be augmented by wrapping with neural conduit and/or topical tissue sealant.
- Close the skin. Avoid pressure on the vessels. Use full-thickness skin grafts

from the lower abdomen to close any remaining open wounds (**TECH FIG 7C,D**).

- Apply a bulky protective dressing and a stable sugar-tong splint with the elbow at 90 degrees with just enough of the toe exposed for monitoring.
- Wrap a pulse oximeter–adhesive probe around the toe for continuous monitoring.

TECH FIG 7 • A. Osteosynthesis is complete. Of the three radial metacarpals, the middle metacarpal forms the base of the thumb; the other two adjacent metacarpals have been removed. Plate and screws provide rigid fixation. **B.** The vascular anastomoses in the example patient demonstrate an end-to-side arterial anastomosis to the radial artery (*white arrow*)

and two separate end-to-end venous anastomoses (*black arrows*). **C,D.** Radial and ulnar views, respectively, of the example case after skin closure. The ulnar-based flap has been trimmed and inset. The open wounds have been covered with full-thickness skin grafts from the lower abdomen.

PEARLS AND PITFALLS

Surgical management

- Have low threshold to obtain angiogram in cases where the foot anatomy may not be normal, eg, congenital cleft.

Technique

- Exposure of a plantar-dominant system is made easier by performing the metatarsal osteotomy early on.
- Meticulous closure and protection of the donor site helps to avoid wound-related problems that can take weeks to heal. Skin grafts are much better tolerated on the hand than the foot.
- Once the toe is disconnected from the foot, a lot of preparation work is needed prior to performing the vascular anastomosis. Ensure that as much of this preparation as possible is performed prior to introducing ischemia. Do not rush through this part, as the osteosynthesis and balancing of tendons are critical for future function.
- Although some surgeons prefer to avoid skin grafting directly over vessels, sometimes this practice is unavoidable after toe transfer. The authors have performed this practice many times without any untoward consequences.

Postoperative monitoring

- There are multiple options for postoperative monitoring: these include clinical assessment of capillary refill and warmth as well as handheld or implantable Doppler probe assessment of pulses. The authors prefer using a continuous pulse oximeter as a monitor as its use is simple and its monitoring of vascularity is reliable.

POSTOPERATIVE CARE

- Admit the patient to a high-level care unit and monitor the toe once per hour, assessing capillary refill, turgor, and warmth.

- A small opening can be left in the dressing where a site distal to the anastomosis can be monitored with a handheld Doppler.
- A continuous pulse oximeter is cheap, accurate, widely available, and highly reliable. Pulse wave changes are indicative of arterial compromise, whereas saturation changes may signal venous compromise.⁴
- Adequate pain control is important postoperatively. Regional anesthesia with indwelling catheters can provide both pain control and sympathetic block, which may help with perfusion.
- The authors use aspirin for 30 days routinely to avoid unwanted platelet aggregation.
 - No other anticoagulants are used unless there are problems with the anastomosis or abnormal clotting early on.
- After several days, the dressings and splint are removed and a well-padded cast is applied. The patient can then be discharged.
- No weight bearing should be undertaken with the lower extremity for 3 weeks.
- The casts are removed after 3 to 4 weeks; weight bearing, hand therapy, and range-of-motion exercises commence at this time.

OUTCOMES

- Outcomes after toe transfer for congenital absence of the thumb are very good.
 - Patients with amniotic constriction bands and a stable CMC joint with solid metacarpal base tend to have the best outcomes because the proximal structures are normal and present.
 - Those with congenital absence do not have as good outcomes because structures may be abnormal or absent proximally.
- In large series of toe transfers,^{1,5-8} most investigators have found that mobility and sensation are satisfactory and function and appearance show significant improvement.
 - The toe does grow, though not to the same extent as a normal thumb.
 - Most parents and patients are very satisfied with function and appearance.

COMPLICATIONS

- Vascular compromise can be due to arterial or venous problems. In most series, about 5% to 10% of patients require take-back for vascular compromise, but most of these toes are salvaged with prompt return to the operating room.
 - The main steps to minimize vascular compromise are in the setup prior to performing the anastomoses.

- These include atraumatic dissection, appropriate pedicle length, avoiding vein grafts (if possible), and minimizing sharp turns, kinks, and external pressure from tightly closed wounds.
- Wound complications can occur, especially on the foot. Meticulous technique in harvesting, tension-free skin closure, and adequate postoperative immobilization can minimize these issues.
- Long-term functional problems can include poor growth, flexor/extensor imbalance, inappropriate length, problematic positioning, and poor sensory or motor return. Tendon transfers, osteotomies, and other operations can alleviate some of these problems, but they can be challenging to perform.

68 Reconstruction of Amniotic Constriction Bands

CHAPTER

Amir H. Taghinia

DEFINITION

- Amniotic constriction band (ACB) refers to the clinical manifestation of an unknown insult that results in predictable phenotypic patterns including bands around limbs and digits, oligodactyly, acrosyndactyly, lymphedema, and other conditions.
- The etiology, terminology, and nosology of this condition have been debated in the literature for years, resulting in no less than 34 different names for this condition.¹ As some others do,^{1,2} the author prefers *amniotic constriction band*, as this terminology conveys the most accurate description and most widely accepted etiology.

ANATOMY

- Extremity anatomy can be quite variable, and in fact, no two cases are the same.
 - The bands may be circumferential (rings) or incomplete, and the anatomic presentation may include amputation, hypoplasia, nail deformities, joint deviations, stiffness, and coalescence of the digits termed *acrosyndactyly*.
 - Usually, the anatomy proximal to the constriction band is normal.
- Patterson³ classified the extremity findings:
 - Type 1—mild digital groove with normal distal extremity
 - Type 2—deeper ring with distal deformity, including atrophy or lymphedema
 - Type 3—syndactyly with fusion of the distal parts, termed *acrosyndactyly* or *fenestrated syndactyly*
 - Type 4—amputation distal to the constriction band
- Syndactyly in this condition is different from developmental syndactyly, which

is caused by failure of apoptosis and is always present proximally. In typical syndactyly, the involvement proceeds proximal to distal and the digits are normal length, whereas the opposite is true in ACB.

- Constriction bands can affect underlying muscles, tendons, nerves, and vessels.
- Urgent release is indicated in cases of ischemia or severe (or worsening) lymphedema.

PATHOGENESIS

- The cause of this condition is unknown, and potential etiologies are still debated. Three main theories have been proposed²:
 - The intrinsic theory implicates a germline developmental abnormality. It helps to explain the craniofacial, body wall, and internal organ anomalies seen but fails to sufficiently explain the patterns of limb findings.
 - The vascular theory advocates that a traumatic insult may disrupt development by disrupting blood flow, with the timing during gestation determining the anomaly.
 - The extrinsic theory best explains the limb manifestations. It maintains that a rupture of the amniotic sac creates mesodermal bands of tissue that entangle limbs and cause the characteristic findings.

NATURAL HISTORY

- ACB occurs in 1200 to 15 000 live births.
- It is more common in females and is likely to occur more frequently in African Americans as compared to Caucasians.
- It is not considered a familial condition.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Newborns who need relatively urgent care can present with either progressive limb ischemia or lymphedema due to a tight band. Ischemia is a surgical emergency, and the band should be treated quickly to avoid limb loss. Worsening lymphedema should also be treated quickly because it can go on to cause ischemia if treatment is delayed.
- Infants who present electively should be evaluated for limb involvement. Digits and limbs involved, depth, presence of syndactyly, stiffness, joint deviation, and distal manifestations should be documented (**FIG 1**).
- Other potentially associated conditions should also be noted, especially those

that impact the general health of the child and may influence anesthetic safety.

IMAGING

- Plain radiographs are the study of choice, though they are not needed in mild cases where the distal limb is normal (**FIG 2**).
- For complex syndactyly cases, plain radiographs with multiple views are critical for surgical planning of separation.
- Other imaging modalities may be needed if nerve, vessel, tendon, or muscle compression is suspected.

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis includes symbrachydactyly, cleft hand, and transverse deficiency.
- Another condition that can mimic ACB is ectrodactyly, ectodermal dysplasia, and cleft lip and palate (ECC) syndrome.

FIG 1 • A 9-month-old girl (the example case throughout) with multilimb ACB. **A,B.** Dorsal and palmar views of her left hand demonstrate “overlapping” fenestrated syndactyly. **C.** The middle finger deviates ulnarly, lying palmar to the ring and small fingers, which are short and tightly adherent. There are fenestrations (tracts/pits) located proximally in the third and fourth web spaces. **D,E.** Dorsal and palmar views of her right

hand demonstrate distal fenestrated syndactyly. **F,G.** Medial and lateral views of her left lower extremity show significant involvement. The leg has two adjacent deep bands, and there are multiple bands around the toes.

NONOPERATIVE MANAGEMENT

- Minor bands may not need operative intervention. This determination is subjective and based on the experience of the surgeon.
- As the infant grows and becomes more ambulatory, the subcutaneous fat that accentuates the band gets absorbed and most minor bands improve significantly in appearance.

SURGICAL MANAGEMENT

- Urgent intervention is needed in cases of vascular compromise or worsening lymphedema soon after birth. For other cases, usual time of surgery is around late infancy or early childhood. In treating bands, the surgeon should take advantage of extra subcutaneous tissue and elastic skin in the young child.
- The treatment of this condition includes repair of the band and the fenestrated syndactyly. The main goals of treatment are to improve appearance and function.
- Multiple approaches have been advocated for repair of the band. These include a variety of rearrangement schemes of skin and subcutaneous tissue. Many of these options are effective at releasing the band.
- The author advocates the adipofascial advancement technique first proposed by Upton.⁴ The band is excised and skin flaps are elevated; extra fat is removed, and adipofascial flaps are elevated and closed as a separate, distinct layer underneath the skin.

FIG 2 • Plain film radiographs of the example case demonstrate ulnar deviation of the middle finger of the left hand **(A)** and foreshortened digits on the right hand **(B)**.

- Similar to others,⁵ the author prefers to avoid Z-plasties, especially in narrow bands where excellent contour can be obtained with flap advancement and linear closure. In cases where the band is wide and adequate contour cannot be obtained (see Technique section), Z-plasties can be placed on the lateral and medial aspects of the limb/digit.⁴
- In most cases, it is safe to repair circumferential bands in one stage, especially if the band is not too deep.
- In general, however, the deeper and more distal the band, the less safe it is to perform a circumferential repair. Circumferentially releasing deep bands in the digits may predispose to venous insufficiency as dermal drainage may become impaired.
- Another indication to perform staged repair is when two bands are in close proximity.
- In most cases of fenestrated syndactyly, there are no flexion or extension creases in the area of the syndactyly. As such, there is little need to do zigzag incisions.
- The author releases most cases using straight-line incisions and covers the wounds with full-thickness skin grafts.

- If bands are released at the same operation, one can consider using discarded skin from the bands for skin grafting. However, this skin tends to be somewhat thicker, and it does not take as well as thinner grafts from the lower abdomen.

Preoperative Planning

- Review radiographs again.
- In cases of deep bands that seem fixed to the underlying bone, one should consider assessing distal blood flow with a Doppler probe. An Allen test is important in cases of deep distal forearm bands.

Positioning

- The patient is positioned supine with the arm out on a small hand table.
- The lower abdominal area is squared-off with Steri-Drapes for skin grafts, if needed for treating fenestrated syndactyly.
- Incisions are planned carefully before the tourniquet is applied.

TECHNIQUES

■ Adipofascial Advancement

Markings and Flap Creation

- The markings dictate where flaps will advance. Push the edges of the band together and mark the area of skin excision (**TECH FIG 1A**).
- The operation is easier and results are better when there is ample subcutaneous tissue and when the band is narrow rather than wide (**TECH FIG 1B,C**).
- Make the skin incisions and remove the intervening skin but leave all of the subcutaneous fat. Any tendon adhesions or nerve or vessel compression can be relieved at this point.
- Elevate skin flaps proximally and distally.
- Elevate adipofascial flaps in the areolar plane just above the extensor mechanism or fascial plane.
- Excise and discard any excess fat.

Advancing Flaps and Creating Z-Plasties

- Suture the adipofascial flaps together. Use a horizontal mattress technique so as to evert the edges and create additional tissue redundancy under the skin incision (**TECH FIG 2**).
- Plan and create Z-plasties to gain additional circumference for the closure (**TECH FIG 3**).
 - Plan these so the transverse limb falls in the midlateral aspect of the limb or digit.

Closure

- Close the skin with everting horizontal mattress 6-0 chromic gut sutures for the digits (**TECH FIG 4A–D**).
- More proximal limb bands are repaired using deep dermal and running intradermal absorbable sutures (4-0 and 5-0 Monocryl) (**TECH FIG 4E**).
- Immobilize with a long extremity cast for 3 weeks.

TECH FIG 1 • A. Incision planning for bands. The surgeon can push the edges together and draw one line where the edges meet. When the edges are allowed to retract, two lines result where the incisions should be made. **B,C.** Narrow vs wide bands. To

achieve normal contour, wide bands **(B)** require a larger section of the band to be removed (*dashed lines*) as compared to narrow bands **(C)**.

TECH FIG 2 • Technique of adipofascial flap and skin advancement for correction of bands. The band is excised **(A)** and separate skin and adipofascial flaps are raised **(B)**. Unnecessary fat is excised and the adipofascial flaps are advanced and closed. **C**. The skin is closed as a separate layer away from the adipofascial flap closure line.

TECH FIG 3 • Theoretical basis of using Z-plasties for treatment of amniotic constriction bands. Z-plasties performed at the edge increase the circumference of the band. **A**. This is useful in wide bands where the entire band cannot be excised but unnecessary for narrow bands. Z-plasties are performed (only two are shown in **B**, but multiple can be performed), lengthening the circumference and allowing improved contour (**C**).

TECH FIG 4 • Immediate postoperative clinical images of the example case showing dorsal **(A)**, radial **(B)**, palmar **(C)**, and web space **(D)** views after correction of thumb and index finger constriction bands and release of third web space fenestrated syndactyly and coverage with full-thickness skin grafts. **E.** Anterior view after repair of medial leg band. These were two adjacent deep bands, and thus a staged approach

was undertaken. The medial bands were treated in one stage by removing the intervening skin between the two bands. The lateral bands were treated in a second stage, preserving the intervening skin, because the band was wider on the lateral aspect.

■ Release of Fenestrated Syndactyly

- Release the fenestrated syndactyly using straight-line longitudinal incisions. In most cases, there are no functional joints in the area where the fingers are joined.
 - Accordingly, the surgeon should not worry about flexion contractures due to straight-line incisions.
- In cases where the syndactyly is distal, the resulting wounds can be closed or skin grafted (**TECH FIG 5**).
- In more proximal cases, the fenestration can be a narrow tract that communicates dorsal and palmar pits (see **FIG 1A,B**). Place a lacrimal probe into this tract.
- Release the syndactyly up to this tract. This degree of release is sufficient in most cases; however, if the tract is too distal, additional release can be performed with standard commissure flaps and full-thickness skin grafts.
- Apply skin grafts to the open wounds (see **TECH FIG 4C,D**).
- Apply a standard syndactyly release dressing with antibiotic-impregnated gauze, moist cotton, and gauze wrap.
- Immobilize with a well-padded long extremity cast.

TECH FIG 5 • Postoperative image after release of fenestrated syndactyly of the right hand. The wounds were small and could be closed primarily.

PEARLS AND PITFALLS

Surgical management

- The older infant or younger toddler is an ideal candidate for repair because there is ample subcutaneous fat and highly elastic skin.
- Mild, shallow bands can be treated conservatively and usually improve with observation as the child grows.
- If releasing the band is done to improve appearance (as in most cases), by performing the operation, the surgeon and patient are choosing to trade one appearance for a better one. This issue should be kept in mind, as sacrifices in technique and approach may be necessary to maximize overall appearance. For example, it may be worthwhile to accept a small bit of contour depression to avoid multiple zigzag incisions in a conspicuous area.

Technique

- In treating bands, the primary focus should be to improve contour. Overall appearance is much more influenced by contour than by scar.
- Be meticulous about hemostasis as hematoma under advanced skin

flaps can cause ischemia and tissue loss.

- The proximal tract in fenestrated syndactyly may be located too distally—in these cases, plan a standard syndactyly release using commissure flaps and skin grafts. Make sure to excise the epithelial tract.

POSTOPERATIVE CARE

- Remove the cast in 3 weeks.
- Start range of motion exercises
- In cases of syndactyly release, refer the patient to hand therapy for fabrication of splint and web space pressure conformer to be used at night for about 1 month.

OUTCOMES

- Functional outcomes after treatment of this condition are fully dependent on the preoperative degree of involvement. Function is much more likely to be determined by the presence of any congenital amputations as compared to minor bands or syndactyly.
 - Because each patient is different, comparative functional outcomes are difficult to standardize.
- Aesthetic outcomes are dependent on the preoperative status of the bands and the technical execution of the repair (**FIG 3**).
- Unfavorable outcomes include contour depression, significant scarring, and contractures.

COMPLICATIONS

- In repair of bands, complications include flap ischemia or distal limb ischemia. Flap ischemia occurs as a result of overzealous undermining, too much tension, or hematoma. Venous insufficiency can occur when deep circumferential digital bands are treated in one stage.

FIG 3 • Long-term postoperative photographs of the example case. **A,B.** Dorsal and palmar view of the hands. **C.** The digits of the left hand are short and stiff, as shown in the clenched fist view. **D.** The leg shows significant improvement in contour of the leg (note one medial scar and two lateral scar; see **TECH FIG 4E**) and toes after two-stage correction. The patient is fully ambulatory.

- Typical complications after syndactyly repair can be seen. These include flap ischemia, skin graft loss, and web creep. Careful planning and meticulous execution can avoid these complications.

69 Centralization for Radial Longitudinal Deficiency

CHAPTER

Amir H. Taghinia, Brian I. Labow, and Joseph Upton

DEFINITION

- Radial longitudinal deficiency (RLD) is a congenital condition characterized by hypoplasia of the radial side of the hand, wrist, and forearm. The bony, articular, and soft tissue structures can be affected in various degrees.
- RLD encompasses a spectrum of conditions ranging from minimally affected radius and normal hand to complete absence of radius and thumb. In some instances, other digits on the affected limb can also be involved—most significantly the index finger, which can be hypoplastic.
- The degree of severity lessens with progression from the radial to ulnar side of the hand.

ANATOMY

- The radius can be mildly foreshortened, significantly hypoplastic, or completely absent. In the most severe cases, the radius, radial carpal bones (scaphoid and trapezium), and thumb are absent. Elbow and (to a lesser extent) shoulder abnormalities can also be present.
- The most common manifestation is an absent radius or a small proximal remnant. In these cases, a tough fibrous anlage is present that connects the proximal radius to the carpal region and distal ulna (**FIG 1**).
- The ulna may be bowed, and its distal end is widened.
- The absence or hypoplasia of the radial structures is accompanied by radial deviation and radial-palmar displacement of the wrist. This positioning weakens flexion power of digits and wrist.
- When the thumb is severely affected, the index finger is usually stiff and hypoplastic. This is clear on physical examination as the finger is usually

thinner, slightly flexed with poorly developed flexion and extension creases.

- The ulnar digits and ulnar muscles tend to be normal, so children manipulate objects with their ulnar digits.
- The flexor carpi radialis and extensor carpi radialis brevis and longus may not be distinctly present. They are usually joined together to form a single set of muscles dubbed “dorsoradial muscle mass.” These radial extensors of the wrist may be poorly developed or nonfunctional. In contrast, the ulnar-sided flexors and extensors are usually present and functional (see **FIG 1**).
- The radial nerve usually ends proximally around the elbow. The median nerve is radially and dorsally displaced, lying superficially on the radial aspect of the wrist.
 - During surgical exposure, the median nerve is superficial over the radial incision and is often mistaken for a tendon. One must recognize and protect this cordlike structure, the median nerve, during surgery. In addition to providing sensation to the radial palm, this nerve also supplies sensation to the usual areas of radial nerve distribution. For this reason, it is often dubbed the “radian” nerve.
 - The radial artery is absent or hypoplastic, but a median artery is present instead.
- RLD is classified based on the degree of involvement. The original Bayne and Klug classification remains widely accepted (**FIG 2**), though a few modifications have been introduced. Types III and IV are the most common.
 - Type I—Minimal radial shortening of 2 mm as compared to ulna. The elbow is normal and the thumb is present, though possibly hypoplastic.
 - Type II—Radius is hypoplastic (“radius in miniature”), wrist is deviated, ulna is bowed, and thumb and radial carpal bones are absent.
 - Type III—The radius is partially absent, usually the distal two-thirds. The thumb and radial carpus are severely affected. A fibrous anlage is associated with flexion and pronation of the wrist.
 - Type IV—The radius is absent and the wrist is severely deviated—sometimes beyond 90 degrees. The thumb is usually absent. Often a small remnant of proximal radius will ossify during the adolescent growth spurt.

FIG 1 • Wrist and forearm anatomy in radial longitudinal deficiency (type III is shown). The fibrous anlage, a remnant of the radius, tethers the wrist radially. The radial wrist extensors and flexors fuse into a “dorsoradial muscle mass.” The radial carpal bones are absent as is the thumb.

FIG 2 • Bayne and Klug classification of RLD. **A.** Radial deviation and palmar subluxation are worse with increasing hypoplasia of the radius. **B.** Representative radiographs of RLD types I to IV.

- Modifications to the original classification system includes introduction of three additional types:
 - Type N—Thumb hypoplasia with normal radius
 - Type 0—Absent or hypoplastic carpal bones with normal radius
 - Type V—Humeral abnormalities

PATHOGENESIS

- RLD occurs in 1 in 30 000 to 1 in 100 000 live births. Bilateral and unilateral cases occur in equal frequency.
- The cause of RLD is unknown. Environmental and genetic factors are likely responsible for developmental anomalies in the apical ectodermal ridge (AER)

between the 4th and 7th weeks of gestation. Animal models with radial deficiencies can be created by ablation of the radial section of the AER.

- RLD is considered to be a malformation, based on the Oberg, Manske, and Tonkin classification of 2010.¹

NATURAL HISTORY

- If untreated, radial deviation usually worsens and the wrist develops stiffness.
- Radial deviation usually recurs to some extent even after surgical correction unless the ulnocarpal joint has been fused.
- Although the forearm does grow, it usually grows slower than the normal forearm and ends up about 60% of normal length.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The infant's shoulder, elbow, and wrist should be examined.
- The degree of wrist deviation and the capacity for passive correction should be noted and recorded.
- The status of the thumb and the radial fingers should be noted, especially in terms of intrinsic muscle development, passive motion of the joints, flexion and extension creases, and the presence of contractures.
- RLD is frequently associated with other conditions (70%–90%) and the likelihood increases with severity.² Bilateral involvement increases the likelihood of associated conditions by over 30%.
 - Although a long list of possible conditions can occur with RLD, the most common are the VACTERL association, Holt-Oram syndrome, craniofacial microsomia, and Fanconi anemia.

IMAGING

- Plain radiographs delineate the degree of involvement and help with classification.
- The hand-forearm angle (HFA) and the hand-forearm position (HFP) should be measured on the anteroposterior radiograph (**FIG 3**).
 - HFA is the angle between the longitudinal axes of the long finger and the distal ulna.
 - HFP is the shortest distance between a line drawn through the longitudinal axis of the distal ulna and the proximal pole of the fifth metacarpal.
- These measures can be followed over time and growth to assess long-term success of surgical correction vs nonoperative treatment.

DIFFERENTIAL DIAGNOSIS

- Thrombocytopenia-absent radius (TAR) syndrome is a genotypically distinct entity, although the treatment is similar.
- Patients have hypomegakaryocytic thrombopenia with a completely absent radius. In contrast to RLD with absent radius (type IV), patients with TAR have thumbs.
- TAR is an autosomal-recessive condition linked to a defect in chromosome 1q21.1.
- Clinical findings include bruising, hemorrhage, and cardiac and renal anomalies.
- The thumb is biphalangal and contains varying degrees of skeletal and thenar muscle hypoplasia.

FIG 3 • Measuring hand-forearm angle (HFA) and hand-forearm position (HFP) on the plain radiograph.

NONOPERATIVE MANAGEMENT

- For most patients, nonoperative management with splinting and stretching is instituted early in infancy.

- This type of treatment maybe a long-term solution for those with mild RLD (types 0, I, and II) or a short-term “bridge” solution in preparation for subsequent surgery (types III and IV).
- The family performs stretching about 8 to 10 times per day by applying longitudinal traction and ulnar deviation.
 - A form-fitting radial gutter splint is then used to keep the wrist in the corrected position.
- Early on, as the family strives for a neutral wrist, the splint will need to be worn at all times and will need frequent revisions. Once the wrist is passively correctable to neutral, the splint can be weaned to night use only.
- Splinting is also a critical postoperative adjunct to keep the wrist in neutral; as the natural history of this condition is progressive radial deviation of the wrist with growth.
- Treatment may not be indicated at all in the following:
 - Adults who have adapted well
 - Patients who cannot tolerate stretching and splinting (eg, develop hygiene problems such as rash)
 - Patients in whom operative treatment poses unnecessary medical risk
 - Patients whose function will worsen with a straight wrist (eg, patients with stiff elbows who may be unable to wipe or feed themselves with the hand).

SURGICAL MANAGEMENT

- Types 0, I, and II RLD are usually treated with stretching and splinting. In rare instances where these measures are ineffective, surgical management can include tendon transfers and/or distraction lengthening.
- Types III and IV RLD can be treated with stretching and splinting first, as a “bridge” intervention, to bring the wrist into neutral prior to formal repair. However, this intervention alone is usually not sufficient to allow the carpus to translate beyond the distal ulna.
- In most cases, preoperative soft tissue distraction is necessary to achieve satisfactory positioning.² This procedure involves application of a (usually) uniplanar distractor without an osteotomy. Once slow distraction (1 mm/d) moves the carpus beyond the distal ulna, formal centralization or radialization can be performed (**FIG 4**).
- In early reports, centralization involved resection of the distal ulna, but this led to early growth arrest. Thereafter, carpal resection was introduced (carving a notch in the carpus to accommodate the distal ulna), which helped with

alignment and avoided growth arrest, but led to stiffness and recurrence.

- To remedy these issues, Buck-Gramcko introduced radialization, which involves:
 - Stabilization of the radial carpal column onto the distal ulna without carpal resection.
 - Transfer of the dorsoradial muscle mass ulnarly to counteract the deforming forces and provide long-lasting correction.
- There is debate about what constitutes centralization vs radialization.
 - Traditionally, centralization involves carving of a carpal notch for insertion of the ulnar head and alignment of the base of the third metacarpal with the central carpus and the distal ulna (**FIG 5A**).
 - In contrast, radialization involves alignment of the second metacarpal with the radial carpus without carpal resection (**FIG 5B**).
- There continues to be disagreement about which of these options is best. Some argue that stabilization of the wrist (radialization) without a carpal notch does not provide a stable equilibrium, whereas others prefer to preserve motion and avoid shortening.
- Nevertheless, most surgeons agree that for the operation to be effective:
 - The fibrous anlage and dense soft tissues should be released or excised.

FIG 4 • The process of soft tissue distraction is demonstrated. The deficient forearm reaches about 60% of the length of a normal one.

- The dorsoradial muscle mass should be transferred to the ulnar wrist.
- Alignment should be maintained with a pin that is kept in for several months, if not longer.
- Microvascular free toe joint transfer involves transfer of vascularized osseous structural support to stabilize the radial column of the wrist. Soft tissue distraction is usually necessary to align the wrist and create a “space” into which the toe will be placed. The metatarsal and proximal phalanx of the second toe are transferred with their growth centers and attached to the distal ulna.
- Although technically demanding, the operation provides the advantage of avoiding injury to the distal ulnar physis and preservation of wrist motion.
- The time to perform corrective surgery is about 1 year of age, barring small patient size and/or associated comorbidities.

Preoperative Planning

- Review risks, benefits, and expectations with parents on the day of surgery. Specifically outline the risks of possible wrist stiffness, poor growth, and persistent or recurrent deviation.
- The long-term outcomes and natural history of this condition should be discussed well before the operative date.
- Fluoroscopy, drills, and pins will be required for the procedure.

Positioning and Approach

- The patient is positioned supine with the arm out on a small hand table.
- Incisions are planned carefully prior to use of the tourniquet.
- A transverse dorsoulnar approach is usually undertaken. There is usually no need to extend incisions along the entire dorsal forearm.

FIG 5 • Centralization vs radialization. A. For centralization, a transverse distal wrist incision is made, the “radian” nerve identified, and the tight radial fibrous anlage released. All tethering soft tissues must be release. A small notch is carved into the carpus to allow introduction of the ulnar head. The wrist is reduced and stabilized with a pin aligning the third metacarpal with the ulnar head. The ECU is advanced. The dorsoradial muscle mass is transferred to the ulnar wrist extensors.

A corrective osteotomy of the ulna may be necessary if the bowing is significant. Excess skin on the ulnar side of the wrist is excised. **B.** In radialization, the maneuvers are similar to those for centralization except that the carpal bones are not excised. Instead, the carpus is stabilized over the distal ulna and held there with a pin. The hand is more ulnarly deviated to provide a better moment arm for the musculature to keep the wrist in the proper posture. The pin aligns the second metacarpal with the distal ulna.

TECHNIQUES

■ Preoperative Soft Tissue Distraction

- Consult manufacturer instructions for application of distractor of choice.
 - The authors prefer a uniplanar distractor as it is easy to apply and manage and effective at achieving the desired result.
- If the wrist is not passively correctable to 50 to 60 degrees of radial deviation (**TECH FIG 1A,B**), a concomitant releasing procedure may be necessary to obtain adequate alignment for placement of the distractor.
 - In this case, plan a transverse incision dorsally on the ulnocarpal joint for exposure of the radial fibrous anlage and tethered soft tissues.
- Plan small longitudinal incisions over the third metacarpal and the proximal ulna. Plan the length of these incisions based on the length of the distractor clamp that will house the pins. Assemble the apparatus and obtain all needed parts before the tourniquet is inflated.
- Exsanguinate the upper extremity.
- If performing a release, make the dorsal wrist incision and expose the fibrous anlage from the dorsal approach (**TECH FIG 1C**).
 - Take care to avoid injury to the “radian” nerve and the extensor tendons.
 - Release the tough radial soft tissues (**TECH FIG 1D**).
- Incise over the third metacarpal and the proximal ulna. Spread the soft tissues; retract and protect any longitudinally running vital structures (tendon,

muscle) until down to bone.

- Insert one pin into the metacarpal and another into the ulna.
- Arrange the distractor clamps onto the pins and tighten slightly. Apply the lengthening bar while manually distracting the wrist; secure the clamps onto the bar.
- Insert another pin into the metacarpal and one more into the ulna, each into the second seat of the respective distractor clamp.
- Loosen the clamps from the bar. Distract the soft tissues as much as possible and secure the clamps back onto the bar tightly.

TECH FIG 1 • Preoperative clinical (**A**) and radiographic (**B**) images of 6-month-old girl with type IV RLD. **C**. If the wrist is tight and significantly radially deviated, the fibrous anlage and tough tethering tissues should be released prior to placing the distractor. **D**. Releasing these structures allows proper alignment of the distractor and makes the process of distraction smoother. **E,F**. After soft tissue distraction and immediately prior to centralization, the deviation and subluxation of the wrist has been corrected.

- Close all the wounds and apply a soft dressing.
- The family can start distraction at 1 mm/d in about 3 to 4 days.
- Instruct the family on how to perform pin-site care to avoid infection. Provide written instructions and a timetable or turning the screw, and mark the distance between the pins so they can see the progress (and avoid

turning the wrong way).

- It helps if they send weekly pictures via e-mail so the surgeon can monitor the progress.
- Once the carpus has translated beyond the distal ulna, leave the distractor on without distracting for another several weeks.
- At that point, the patient will be ready for formal centralization or radialization (**TECH FIG 1E,F**).

■ Centralization or Radialization

- If preoperative distraction has been performed, the distractor can be removed at the time of the centralization or radialization procedure.
- A transverse dorsoulnar incision is planned over the ulnocarpal joint. Extra skin should be reserved until the end where the exact amount can be carefully assessed prior to removal.
- The authors do not routinely employ local Z-plasty or transposition flaps. The use of preoperative soft tissue distraction has virtually eliminated any problems with skin deficiency.
- Exsanguinate the extremity.
- Incise the skin; identify and protect any veins that can be saved. Identify the fibrous anlage, the radial nerve, the dorsoradial muscle mass, the extensor tendons to the digits, and the extensor carpi ulnaris tendon.
- The radial nerve is usually radiodorsally translated and located just under the skin on the radial aspect of the wrist (**TECH FIG 2A–C**).
- Release the fibrous anlage and the dorsoradial muscle mass. Release any other tight investing fascia.
- Release the extensor carpi ulnaris from its attachment on the fifth digit metacarpal. This tendon will be advanced to provide more ulnar pull.
- Incise the wrist capsule transversely.
- If performing traditional centralization, carve a small notch into the carpus to accommodate the distal ulna. Otherwise, no carpal resection is needed.
 - Align the third metacarpal (centralization; see **FIG 5A**) or second metacarpal (radialization; see **FIG 5B**) with the distal ulna.
 - A 0.062-in. Kirschner wire can now be passed antegrade through the wrist entering the base of the chosen metacarpal. The authors prefer to insert the pin obliquely to avoid the metacarpophalangeal joint. Thus, the

pin would come out of either the first (if second metacarpal) or second (if third metacarpal) web space.

- Insert the distal ulna into the carpal slot (centralization) or stabilize the carpus over the distal ulna (radialization). Drive the K-wire down the ulna in retrograde fashion.
- If necessary, perform an opening wedge ulnar osteotomy to correct any bowing of the ulna and drive the pin further proximally to secure this osteotomy.
- Close the wrist capsule securely.
- Advance the extensor carpi ulnaris and reattach to the base of the fifth digit metacarpal. Transfer the dorsoradial muscle mass to the extensor carpi ulnaris tendon to provide additional ulnar moment arm to the wrist.
- Excise any redundant skin and close using absorbable sutures. Apply antibiotic-impregnated gauze to all incisions and cover with sterile gauze. Wrap loosely.
- Apply a long-arm cast.

TECH FIG 2 • Preoperative clinical (**A**) and radiographic (**B**) images of an 8-month-old boy with type IV RLD showing significant deviation. His family declined preoperative soft tissue distraction but did perform stretching and splinting such that the wrist could be passively corrected to 20 degrees of radial deviation. The “radian” nerve is the most superficial structure on the radial side of the wrist. **C**. It is demonstrated here under the green background. A smaller dorsal sensory branch (sensory radial nerve equivalent) is looped and visible dorsally (*black arrow*). The expected path of the nerve was marked on the skin preoperatively (*white arrow*).

PEARLS AND PITFALLS

Technique

- The pins may be left in for a long time; in fact, some surgeons leave the pins in for a year or longer. Although this may increase stability, it decreases range of motion and can result in physeal injury and hardware failure.
- The “radian” nerve is the most superficial structure on the radial side of the wrist; the surgeon should be cautious to avoid injury while dissecting in this area.

Postoperative

- Cast immobilization time should be limited, only to allow the soft tissues to heal. These children have short forearms and can easily escape from their casts.

Therapy

- It is critical to instruct the parents to move the fingers passively during preoperative soft tissue distraction. This action prevents stiffness and contractures.

POSTOPERATIVE CARE

- Remove the cast after 2 or 3 weeks and apply a thermoplast splint. Range-of-motion exercises of the digits can be started at this time.
- Leave the pin in for 8 to 10 weeks.

OUTCOMES

- Long-term outcomes for the two cases depicted are shown in **FIG 6**.
- The main unfavorable outcome seen after centralization or radialization is recurrence of the deviation. The recurrence appears to be related to the preoperative degree of deviation and amount of correction achieved postoperatively.²
- Rigorous compliance with night splinting may decrease the risk of recurrence (**FIG 7**).
- Despite the leveling and realignment of skeletal support from the remaining carpus and hand, the muscular imbalance across the wrist remains the primary cause for recurrent deviation.
- Despite the risk of recurrence, Kotwal et al.³ showed that surgical treatment of RLD is sensible. He compared patients who had undergone surgery to those who had not, showing that surgical treatment of RLD improves appearance and

function, and leads to better performance in daily activities.

- Although the focal point of treatment is correction of the radial deviation, the importance of this concern has been questioned. Recent studies have shown that wrist and digit range of motion as well as grip strength and forearm length may be better than wrist angulation in predicting functional outcomes in RLD.⁴
- Hence, it may be worthwhile to avoid carpal resection, thereby sacrificing some loss in position of the wrist in favor of better motion.

FIG 6 • A. The case in **TECH FIG 1** year after radialization. **B,C.** Long-term postoperative images after centralization for the case in **TECH FIG 2**. A carpal notch was required to adequately reduce the wrist.

COMPLICATIONS

- Infections during soft tissue distraction are frequent and range from minor pin-tract infections to cellulitis and, rarely, deep bone infection. These problems are avoided with good pin-site care and close follow-up.
- Other complications with the distraction include inadequate distraction by the parents, device malfunction or malalignment requiring repair, and stiffness and/or contracture of the digits. These problems can be avoided with good parent education and support as well as passive range-of-motion exercises.

- Complications of centralization or radialization include wound infections and hardware problems. Because the pin has to be in place for many weeks, it may migrate, dislodge, or break.
- One of the most concerning complications is early growth arrest of the distal ulna, since it will cause additional shortening of an already short forearm.
- This issue can be avoided by earlier removal of the pin and minimal manipulation of the distal ulna during the corrective operation.
- Physeal damage may also occur with rapid, aggressive distraction in young children.

FIG 7 • Long-term result after centralization. **A.** Initial radiograph showing type IV RLD. After centralization and 12 weeks of pin fixation **(B)** and 14 years later **(C)**. At long-term follow-up, the wrist maintained adequate alignment. This child was compliant with nightly splint use. Note the index finger has been pollicized.

70 Excision of Vascular Malformation of the Hand

CHAPTER

Amir H. Taghinia

DEFINITION

- Vascular anomalies fall into two main categories: tumors and malformations. Tumors, such as hemangiomas, exhibit cellular hyperplasia. In contrast, malformations represent a localized defect in vascular morphogenesis.
- Vascular malformations can be broadly classified into slow-flow and fast-flow lesions.
 - Slow-flow lesions include capillary, lymphatic (LM), and venous (VM) malformations or mixed lesions.
 - Fast-flow lesions include arteriovenous malformations (AVM).

ANATOMY

- Vascular anomalies can occur anywhere in the hand and upper extremity, and can involve all components of soft tissue, bone, and joint. When present, they can alter or distort the normal anatomy.

PATHOGENESIS

- The exact etiology of vascular anomalies is the subject of intense scientific investigation.
- Somatic activating mutations in the phosphatidylinositol-3-kinase (PIK3CA)/mammalian target of rapamycin (mTOR) pathway appear to underlie a number of overgrowth phenotypes with vascular anomalies.¹

NATURAL HISTORY

- Hemangiomas have a biphasic growth phase with proliferation early in life and subsequent involution.
- Malformations have a propensity to slowly expand throughout life.

PATIENT HISTORY AND PHYSICAL FINDINGS

- With a few exceptions, hemangiomas are usually absent at birth or present as a small stain.
- Patients present with a growing, vascular, high-flow lesion in early infancy.
- These lesions have a deep red appearance and strong Doppler signals throughout.
- Vascular malformations can present any time in life. Although they are likely present at birth, they may be clinically silent for years. They usually present with a combination of discoloration, disproportionate growth, swelling, and pain (**FIG 1**).

FIG 1 • **A,B.** AP and lateral views of a growing, painful mass on the palm of a 7-year-old boy (the example case throughout).

FIG 2 • T2-weighted (A) and T1-weighted postgadolinium (B) MRI images of the lesion.

- LMs may also develop drainage or infections, and AVMs can develop paradoxical ischemia and ulceration.
- Most vascular malformations can be correctly diagnosed by physical examination. A multidisciplinary approach to diagnosis and treatment gives the best outcomes.

IMAGING

- Ultrasonography is the best initial radiological examination for these lesions. It can be done in the clinic room during the first multidisciplinary visit. The type and extent of the lesion can be determined quickly and easily.
- For surgical planning purposes, however, more extensive imaging is usually required. An MRI is the best soft tissue imaging tool for these lesions (**FIG 2**). Angiography is helpful for high flow AVMs.

DIFFERENTIAL DIAGNOSIS

- The myriad of multiple overlapping conditions that include vascular malformations can be confusing. Although these lesions can be solitary, the presence of associated conditions is often the rule rather than the exception. For an extensive list of associated conditions, the reader is referred to other readings.²
- Differential diagnosis includes overgrowth conditions, malignancies, and a variety of other benign conditions. When in doubt, biopsy is recommended.

NONOPERATIVE MANAGEMENT

- Hemangiomas are often treated conservatively with no intervention or with medical therapy including steroids and beta-blockers. Surgery has a minimal role in the treatment of these lesions.
- Most malformations are amenable to interventional radiological treatments, which involve sclerotherapy and embolization. Certain lesions cannot be treated this way—notably, microcystic lymphatic malformations—and thus require surgery.
- In the hand and upper extremity, the authors advocate against sclerotherapy of lesions close to neurovascular structures unless surgical resection is deemed to be too morbid. Sclerotherapy around major upper extremity nerves can cause

numbness, motor deficit, and chronic pain.

SURGICAL MANAGEMENT

- The indications for surgical intervention are pain, functional compromise (impending or extant), rapid or persistent growth, ischemia, and ulceration in lesions that are not suitable for treatment by interventional radiologists.
- A few key principles are outlined here²:
 - Plan extensively. Outline the extent of the resection and abide by it.
 - Place incisions thoughtfully. Often multiple debulking procedures may be necessary.
 - Use magnification.
 - Approach the lesion from known to unknown.
 - Avoid vascular compromise. When a critical arterial segment to an extremity is removed, it should be reconstructed.
 - Avoid intraneural dissection. Dissection within nerves often leaves neuromas-in-continuity with disruption of distal sensory or motor function.
 - Avoid partial dissections. Removal of an entire involved area is preferred as it avoids future challenging dissection in a scarred bed.
 - Replace abnormal or ischemic skin; use flaps or skin grafts.
 - Use drains liberally.
 - Amputate if needed. Ischemic, nonfunctional, painful, and parasitic digits or limbs should be removed.
 - Follow patients long term.
- The purpose of surgery should be clearly outlined. In large or complex cases, the goal of surgery is relief of pain and improvement of function. With the exception of small lesions, total eradication of most lesions is impossible. These lesions are not malignant, and so a wide excisional approach that sacrifices normal functioning structures is ill advised.

Preoperative Planning

- Again discuss risks, benefits, and expectations with parents and patient on the day of surgery.

Positioning and Approach

- The patient is positioned supine with the arm out on a hand table.
- Incisions are planned carefully prior to use of the tourniquet.
- In infants and toddlers, an Esmarch bandage is used as a tourniquet because it

is more effective at providing a bloodless field in small arms. In older children, a standard pneumatic tourniquet is used.

TECHNIQUES

■ Excision of Palmar Venous Malformation

- Mark a palmar incision that incorporates the thenar flexion crease (**TECH FIG 1A**).
 - Exposure will be needed beyond the area of malformation to fully expose all the vital neurovascular structures—away from the lesion.
 - Design the incision so that distal or proximal extension of the wounds will be possible.
- Raise skin flaps over the palmar fascia.
- Venous malformations tend to become much smaller when the limb is exsanguinated and the tourniquet is inflated.
- Incise the palmar fascia sharply and explore to find the nerves and vessels proximal to the lesion.
- Isolate the arteries and nerves with vessel loops (**TECH FIG 1B**). Dissect these structures off the venous malformation.
 - For lesions of the palm, it is easier to dissect the ulnar and radial aspects of the lesion first. This way, any vital longitudinal structures that traverse the lesion can be identified, protected, and dissected more easily.
- Use vessel loops not only for identification but also to place traction on vital structures so they can be dissected along their native paths.
- Venous malformations of the digits and distal palm will often arise from the venae comitantes of the digital arteries and thus run along the arteries. Isolate the venous malformation completely with the arteries that traverse it on either side (**TECH FIG 1C,D**).
- Avoid sacrificing arteries. Dissection of the venous malformation off the digital arteries is possible and should be attempted.
 - Perform the dissection with magnification using an operating microscope and micro instruments (**TECH FIG 1E**).
 - Use an ultrafine bipolar forceps (on a low setting) to cauterize all of the branches of the arteries that feed the venous malformation.

- Release the tourniquet and obtain hemostasis.
 - To avoid bleeding postoperatively, the best strategy is to remove all the venous malformation.
 - If subtotal excision is too difficult, the second best strategy is to prophylactically (ie, during the excision procedure) tie or clip the entire portion of the venous malformation that will be left behind.
 - The least favorable (though not always avoidable) strategy is to sharply remove some of the venous malformation and leave some behind with channels wide open. These will bleed a lot and are very hard to control with the tourniquet down. Bleeding should be controlled with a combination of prolonged direct pressure, tissue sealants, and local clotting enhancers.
- Use drains liberally. The author prefers the TLS drain system for digital and palmar lesions. The suction tube can be changed once it is one-third full or every 4 hours.
- A soft gauze dressing is applied followed by a well-padded cast. The cast is bivalved if there is any concern about postoperative bleeding or swelling.

TECH FIG 1 • A. Incision markings. The proximal incision extends into the thenar flexion crease. This incision is made proximal to the lesion to identify the digital nerves and branches of the superficial palmar arch. A Y-type pattern at the distal extension in the web is versatile as this incision can be extended into the digits via midlateral or oblique incisions while keeping the flaps wide-based for optimal vascularity. **B.** The common digital nerve to the second web space

and its branches have been mobilized (*yellow loops*). Proximal incision extension was made to find the superficial palmar arch, which was absent in this patient. The venous malformation is decompressed under tourniquet control. **C.** The venous malformation has been completely mobilized—the green background sits underneath it. The ulnar digital artery to the index finger and the radial digital artery to the middle finger have been identified and looped. These vessels emerge from the malformation. The *blue loop* is around the common digital artery to the second web space. **D.** The common digital artery (*arrow*) can be seen emerging from (the deep arch) underneath the flexor tendon to the index finger and piercing the venous malformation. **E.** The venous malformation can be safely dissected away from the common and proper digital arteries using the operating microscope and microinstruments. The vessels are shown after the lesion has been removed.

PEARLS AND PITFALLS

Diagnosis

- A multidisciplinary approach is the best way to take care of these patients, especially in more complicated cases.

Nonoperative management

- Avoid sclerotherapy of palmar venous malformations.

Technique

- Keep meticulous hemostasis during the case. Once important structures become bloodstained, they can be much more difficult to identify and dissect.

Technique

- Use fine instruments, especially in children who have smaller vital structures in the hand than do adults.

POSTOPERATIVE CARE

- For VMs, the drain can be removed within 24 hours, once the threat of bleeding has faded. For LMs, the drain should be in until drainage has abated significantly. If the fluid collects in the wound, it can coalesce into firm scar and added bulk.
- Immobilize with a cast or a splint for 2 to 3 weeks.
- Discontinue immobilization and start hand therapy.

OUTCOMES

- Outcomes are variable and highly dependent on the initial degree of involvement. In patients with joint and or tendon/muscle contractures, surgery may result in limited improvement.
- For patients with painful VMs, removal usually results in significant improvement in symptoms.³

COMPLICATIONS

- The most common complications are bleeding and skin flap compromise.
 - Bleeding and hematoma can be avoided with meticulous hemostasis and liberal use of drains and hemostatic agents.
 - Skin flap compromise may be caused by inherent disease (vascular steal) or attributed to poor planning and execution. Ischemic flaps should be debrided and replaced with healthy flaps or skin grafts.
- Recurrence and persistent growth are common problems, especially in extensive lesions.
- Distal ischemia is a dreaded complication, especially after treatment of AVMs when the arterial feeders have to be divided.
 - In these cases, it is wise to have a backup plan to bypass with vein grafts if needed.

Section XIV: Tumors

71 Lumps and Bumps of the Hand and Wrist

CHAPTER

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- Ganglion cysts
 - Ganglion cysts are the most common soft tissue tumor of the hand.
 - Though not a true cyst because the lack of an epithelial lining, ganglion cysts are mucin-filled lesions with collagen-lined walls, usually attached to an underlying joint capsule, tendon, or tendon sheath.¹
 - Ganglion cysts are a frequent cause of hand and wrist pain. Sixty to seventy percent of ganglion cysts appear in the dorsal wrist, whereas 18% to 20% of ganglions can be found in the volar wrist.¹
- Mucous cysts
 - Mucous cysts are primarily found in the dorsal distal interphalangeal (DIP) joint and have been referred to as mucous cysts of the finger, mucoid cysts, mucinous pseudocyst, myxomatous cutaneous cyst, synovial cyst, periarticular fibroma, periungual ganglion, epidermal cyst, nail cyst, dorsal cyst, digital myxoid cyst, and cutaneous myxoid cyst.²
 - The lesions may be associated with osteoarthritis of the joint (degenerative mucous cyst).
- Giant cell tumors
 - Giant cell tumors are benign, slow-growing tumors of the tendon sheath, and have also been referred to as fibrous xanthoma, pigmented villonodular tenosynovitis, or localized nodular synovitis.
 - After ganglion cysts, giant cell tumors are the second most common tumor of

the hand.

ANATOMY

■ Ganglion cysts

- Ganglion cysts consist of a solitary or multilobulated cyst sac filled with a clear jellylike mucinous fluid. They are composed of hyaluronic acid, glucosamine, albumin, and globulin.¹
- The lesion originates from an underlying joint or tendon sheath and maintains communication to the cyst sac via a tortuous stalk (**FIG 1**).
- Dorsal ganglion cysts typically originate at the scapholunate ligament, whereas volar ganglion cysts often originate from the radiocarpal or scaphotrapeziotrapezoidal joint, flexor carpi radialis tendon, or A1 pulley.³
- Volar wrist ganglions may be intertwined with branches of the radial artery, complicating surgical dissection.

FIG 1 • A. Communication of a dorsal ganglion through the joint capsule to the underlying scapholunate ligament. **B.** In cases where the ganglion cyst is not directly overlying the scapholunate ligament, it is still connected via a long pedicle. **C.** A multicystic ganglion with intra-articular cysts.

FIG 2 • A. Volar ganglion cyst in situ. **B.** Giant cell tumor of the tendon sheath removed from the volar surface of the long finger.

- Grossly, the lesions are smooth, well circumscribed, white, and translucent (**FIG 2A**).
- Microscopically, the cysts have dense fibrous connective tissue without any true cellular lining. The outer surface is irregular and fibrillated, composed of disorganized collagen fibers.⁴
- Mucous cysts
 - Mucous cysts typically originate at the DIP joint with its stalk passing between the extensor insertion and the collateral ligament.
 - The microscopic appearance is similar to ganglion cysts.
- Giant cell tumors
 - Giant cell tumors are yellow- to brown-colored rubbery lesions that may present with joint involvement or bone erosion (**FIG 2B**).
 - The tumors are typically found on the volar surfaces of the radial three digits of the hand, though dorsal involvement is also common.⁵
 - A type I tumor is a single round or multilobulated tumor entirely surrounded

by one pseudocapsule. Type II tumors consist of two or more distinct tumors not joined or surrounded by a pseudocapsule.⁶

- Histologically, giant cell tumors contain multinucleated giant cells, histiocytes, and hemosiderin deposits.

PATHOGENESIS

- There are multiple theories for the cause of ganglions and mucous cysts. It had been thought that synovial herniation resulted in mucoid degeneration. However, the lack of a cellular lining argues against this theory.
- Another theory is that a stress-induced stretching of capsular and ligamentous joint structures stimulates increased mucin production. The mucin collects in the form of capsular ducts and lakes that eventually coalesce into a main cyst.⁷
- The pathogenesis of giant cell tumors is not completely understood. The most widely accepted hypothesis is that of an inflammatory process leading to a reactive or regenerative hyperplasia.⁸

NATURAL HISTORY

- Ganglion cysts
 - Ganglion cysts typically arise spontaneously and are most frequently found in women between the second and fourth decades of life.
 - Though a history of trauma is rare, local injury may make the patient aware of the presence of the tumor.
 - The size of ganglion cysts may fluctuate with use of the extremity, enlarging with increased activity and shrinking with rest.
 - Ganglion cysts may rupture or disappear without treatment. However, there is no known marker to reliably predict which cysts will resolve spontaneously and which will persist.
 - Spontaneous resolution is more commonly seen in the pediatric population.⁹
- Mucous cysts
 - Mucous cysts primarily occur between the fifth and seventh decades in the DIP joint of the index and long fingers.
 - The lesions are typically associated with osteoarthritis of the joint.
 - An open or draining cyst can become infected leading to septic arthritis of the underlying DIP joint.¹
- Giant cell tumors
 - A giant cell tumor begins as a single nodule but may become multinodular as it enlarges over time.

- Malignant transformation has not been reported.¹⁰

PATIENT HISTORY AND PHYSICAL FINDINGS

- Ganglion cysts
 - Patients often present with an asymptomatic 1- to 2-cm well-circumscribed, slightly mobile, fluid-filled mass.
 - Patients typically report that the mass has been present for months to years with fluctuations in size.
 - Dorsal wrist ganglions most often present with the mass overlying the dorsal scapholunate interval (**FIG 3A**).
 - Volar wrist ganglions commonly appear with a mass between the extensor tendons and the flexor carpi radialis (**FIG 3B**).
 - Volar retinacular cysts involve the tendon sheath overlying the A1 or A2 pulleys and may appear fluctuant or firm with palpation. Though typically asymptomatic, patients may complain of discomfort with forceful grip. Although on examination these lesions may be slightly mobile, they do not typically glide with tendon movement.
 - Patients often seek medical attention for ganglion cysts due to aesthetic concerns.
 - Pain or sensory symptoms secondary to ulnar or median nerve compression can occur. The pain is typically a dull ache and is most pronounced with active hand use.
 - Weakness of grip may be a complaint, particularly with dorsal wrist ganglions.

FIG 3 • **A.** Clinical appearance of dorsal ganglion cyst.
B. Clinical appearance of volar ganglion cyst.

- The fluid within ganglion cysts will transilluminate light, whereas other solid lesions will not.
- Frequently, there is no history of antecedent trauma. However, if there is a dorsal ganglion in the presence of trauma, the exam should include a complete evaluation of carpal stability.
- Mucous cysts
 - Mucous cysts are commonly found over the DIP joint of the long or ring finger as a painless mass lateral to midline on either the dorsal radial or ulnar side of the joint with extension into the eponychial fold.
 - Mucous cysts may make the overlying dermis thin, causing rupture of the skin and drainage.
 - Longitudinal nail grooving or Heberden nodes with DIP joint osteoarthritis can be present in mucous cysts.
- Giant cell tumor
 - Giant cell tumors present as a painless, firm, nodular, nontender, slow-growing subcutaneous nodule.
 - Patients may present with sensory deficits secondary to nerve compression.
 - It typically presents in females in the fourth to sixth decade and is often found on the volar surfaces of the hand, though dorsal involvement is not infrequent. Most often, it is found in the radial three digits and the DIP joint.
 - The lesion is firmer than a ganglion cyst and will not transilluminate light.

IMAGING

- Radiographs are required if the patient complains of pain or there is a history of trauma.
- Plain films are useful in identifying intraosseous ganglion cysts.
- An arthrogram can demonstrate communication between the cyst and the joint space.
- MRI is used to identify an occult ganglion cyst or to localize the site of origin for preoperative planning.
- Mucous cysts often have radiographic osteoarthritic changes in the joint with Heberden nodes
- On plain radiographs, giant cell tumors may demonstrate erosion of bone secondary to mass effect. Although bony erosion may indicate a higher risk of recurrence, bony indentation does not.⁶
- Ultrasonography can aid in detecting giant cell tumor satellite lesions.¹¹

DIFFERENTIAL DIAGNOSIS

- Ganglion and mucous cysts
 - Lipoma
 - Synovial cyst
 - Epidermal inclusion cyst or sebaceous cyst
 - Giant cell tumor of tendon sheath
- Giant cell tumor
 - Tendon sheath fibroma
 - Synovial hemangioma
 - Tophaceous gout
 - Periosteal chondroma

NONOPERATIVE MANAGEMENT

- Ganglion cysts can be treated nonsurgically with rest, splinting, oral analgesics, or aspiration. The injection of lidocaine, hyaluronidase, or steroids can also be employed during aspiration.
- Aspiration treatments yield recurrence rates as high as 59%.¹²
- Volar retinacular cysts that are not associated with a stenosing tenosynovitis have a better response to aspiration/injection, and surgical excision can often be avoided.
- Traumatic rupture with a book (ie, Bible) is only of historical significance.
- Aspiration of nondraining mucous cysts may be performed, but repeat aspiration is not advised to avoid joint infection.
- There is no role for nonoperative management for giant cell tumors.

SURGICAL MANAGEMENT

- For ganglion and mucous cysts, excision is indicated for symptomatic patients and for those who have failed conservative measures.
- Draining mucous cysts should be excised because of the risk of infection, which can ultimately lead to septic arthritis.
- Surgery is indicated for giant cell tumors for appearance, loss of function, or neuropathy.
 - A marginal excision with identification and excision of satellite lesions is necessary.

Preoperative Planning

- Appropriate preoperative imaging should be performed to identify the extent of the lesion, presence of any satellite lesions, or involvement of any vital structures.
- In cases of volar wrist ganglions, an intact palmar arch must be confirmed with a preoperative Allen test.
- Patients with giant cell tumors must be informed of the high recurrence rates.

Positioning

- The patient is positioned supine on the operating table, and the extremity is positioned on a hand table.
- The extremity is prepped and draped circumferentially.
- The appropriate anesthesia is administered (general, regional block, digital block) and an appropriate tourniquet is applied (upper arm or digit).
- The location of the lesion dictates the technique and the approach chosen.

TECHNIQUES

■ Dorsal Wrist Ganglion

- Exsanguinate the extremity and apply an upper arm tourniquet.
- Make a 2-cm transverse incision centered over the dome of the ganglion (**TECH FIG 1A**).
- Dissect the subcutaneous tissues, taking care to identify and protect the dorsal radial and ulnar sensory nerve branches.
- Identify the extensor pollicis longus (EPL) and extensor digitorum communis (EDC) tendons and retract them. Use a self-retaining retractor for exposure. The ganglion is typically in the interval between the third and fourth extensor compartments (**TECH FIG 1B**).
- Free the cyst circumferentially using blunt dissection. If possible, avoid rupturing the capsule, so that it is easier to trace the ganglion to the stalk, which is attached to the dorsal retinaculum (**TECH FIG 1C,D**).
- Identify the stalk connecting the main cyst to the joint. It usually can be found on the dorsal aspect of the scapholunate interosseous membrane just proximal to the dorsal scapholunate ligament.
- Tangentially excise the ganglion with the capsular attachments, without

disrupting the scapholunate ligament. A mucin-filled duct piercing the fibers of the scapholunate ligament connecting the joint with the cyst can be identified (**TECH FIG 1E**). One should not cut into the scapholunate ligament.

- If the ganglion is large, it should first be decompressed. With a no. 15 blade, excise the base of the stalk with a rim of the dorsal wrist capsule.
- To minimize recurrence, cauterize the site of origin of the cyst and the edge of the wrist capsule with bipolar cautery.
- Release the tourniquet, confirm hemostasis, and close the wound in multiple layers. The skin is closed with a nonabsorbable monofilament suture.
- Capsular closure should be avoided to prevent joint stiffness. Place the wrist in slight flexion postoperatively.
- Place the hand in a bulky dressing with a neutral palmar splint. Remove the dressing and sutures in 7 to 10 days.

TECH FIG 1 • A. Typical transverse incision made over the scapholunate ligament. **B.** The dorsal ganglion cyst is most frequently found between the extensor pollicis longus (EPL) and extensor digitorum communis (EDC) tendons. **C.** The incision into the capsule begins on the radial surface of the cyst and continues circumferentially. **D.** A circumferential rim of capsule is taken with the cyst and continued in the volar direction. **E.** The typical relation of the mucin duct with the scapholunate ligament. It is important to include this in the resection to minimize future recurrence.

■ Volar Wrist Ganglion

- Perform a preoperative Allen test to evaluate for radial dominant circulation.
- Make an incision centered over the cyst. This incision is most commonly in the interval between the first extensor compartment and the flexor carpi radialis (FCR) tendon (**TECH FIG 2A**).
- Create skin flaps and place a self-retaining retractor for exposure. Incise the underlying forearm fascia longitudinally.
- While taking care to protect the branches of the lateral antebrachial cutaneous nerve and the radial artery, identify the capsule and trace the pedicle to the volar joint capsule (often the radiocarpal or the scaphotrapezial ligament) (**TECH FIG 2B**).
- If extension into the carpal canal is necessary, avoid injury to the palmar cutaneous branch of the median nerve by not straying ulnar to the FCR tendon.
- In a fashion similar to the dorsal wrist ganglion, open the joint and excise all the capsular attachments along with the cyst (**TECH FIG 2C**).
- If the cyst is adherent to the radial artery, a small cuff may be left behind to avoid arterial injury. It is particularly important to avoid dissecting the ganglion away from the radial artery because a shared wall may be indistinct and injuring the radial artery is likely. Therefore, one should decompress the

ganglion and leave the cyst wall attached to the artery. Then trace the ganglion to the wrist joint for resection and cauterization of the stalk.

- After excision of the cyst, digitally compress the surrounding tissue to rule out additional mucin-filled pockets requiring excision.
- Release the tourniquet, obtain hemostasis, and close the wound with a nonabsorbable monofilament suture. Avoid capsular closure.
- Place a bulky dressing. Remove sutures approximately 7 to 10 days after surgery.

TECH FIG 2 • A. A longitudinal incision spanning from the proximal portion of the cyst to its distal extent. If additional distal exposure is necessary, the incision may be carried out into the carpal tunnel. **B.** Identification of the cyst pedicle toward the volar joint capsule. **C.** Excision of ganglion with all the capsular attachments. (Arrow indicates the FCR tendon.)

■ Mucous Cyst

- Apply a finger tourniquet after obtaining digital block anesthesia.
- If the overlying skin is of good quality, make a gentle curving transverse incision centered over the DIP joint.
- If there is involved overlying skin, make a longitudinal elliptical incision including the overlying skin to be excised (**TECH FIG 3A**).
- Mobilize the cyst and trace it to the joint capsule, excising it with the capsule and any involved skin (**TECH FIG 3B**).
- Often, it will be necessary to excise all the soft tissue between the collateral ligament and the extensor tendon, leaving the DIP joint exposed.
- It is imperative to avoid injury to the germinal nail matrix, the insertion of the extensor tendon, and the collateral ligament.

TECH FIG 3 • **A.** An elliptical incision is used to include the overlying skin when it is involved with the mucous cyst. **B.** The cyst is identified and traced down to the joint capsule. **C.** Closure of defect with nonabsorbable monofilament suture. Sutures are typically removed 7 to 10 days after surgery.

- With the extensor tendon retracted dorsally, explore the opposite side and excise any occult cysts or thickened synovial tissue.
 - Excise osteophytes and hypertrophic synovial tissue with a rongeur to minimize recurrence.
 - Release tourniquet and achieve hemostasis.
 - Close the defect primarily with nonabsorbable monofilament suture (**TECH FIG 3C**).
 - If the skin defect is excessive, a long rotational flap or full-thickness skin graft may be necessary. No excess tension should be placed on the closure.
 - Place the distal joint in a splint, and remove sutures in 7 to 10 days.
-

■ Giant Cell Tumor

- Perform initial exposure using an appropriate incision based on the anatomic location of the mass, and isolate the neurovascular bundle proximal and distal to the mass.
 - After identifying the pseudocapsule, use a Freer elevator to bluntly dissect the surrounding tissue from the lesion (**TECH FIG 4A**).
 - Excise the tumor in total with a margin of normal tissue. If necessary, a portion of the tendon sheath may be excised and the area cauterized with bipolar electrocautery.¹
 - Meticulously examine the local area and excise any satellite lesions to minimize recurrence (**TECH FIG 4B**).
 - If there is joint involvement, perform a capsulotomy and inspect the joint, debriding any pigmented soft tissue. If there is bony erosion, local curettage is necessary. If joint involvement is extensive, arthrodesis may be necessary to ensure complete excision.
 - If the extensor tendon is involved, a portion may need to be excised. In rare cases, a tendon reconstruction can be performed if necessary.
 - Close primarily and place hand in a bulky dressing.
-

TECH FIG 4 • A. The giant cell tumor is dissected with a margin of normal tissue after identifying the neurovascular bundle proximal and distal to the mass. **B.** The local area must be closely inspected to identify and excise any satellite lesions. Failure to do so will inevitably lead to a high likelihood of recurrence.

PEARLS AND PITFALLS

Ganglion cyst

- Adequate excision requires removal of a small cuff of the joint capsule.
- Do not cut into the scapholunate ligament to avoid inadvertent injury.
- Cauterize the edge of the capsule before releasing the tourniquet. It will be very difficult to adequately cauterize it subsequently.
- Do not repair the capsule to avoid joint stiffness.
- Always identify the deep and superficial branches of the radial artery when excising volar wrist ganglion cysts. It may be adherent to the artery.

Mucous cyst

- Adequate excision requires debridement of joint osteophytes and any occult cysts.
- Great care must be taken to avoid nail bed injury even if a small amount of cyst must be left behind.
- Avoid injury to extensor tendon or collateral ligament to prevent postoperative extensor lag or DIP joint instability.
- Evaluate both sides of the extensor tendon and the entire DIP joint to rule out occult cysts.
- Do not close skin flaps under excess tension.

Giant cell tumors

- Satellite lesions must be identified and excised to lower the likelihood of recurrence.
- Perform capsulotomy if there is joint involvement to adequately resect

all involved tissue.

- Take care to identify and protect the neurovascular bundles because the lesion can displace or envelop the neurovascular structures

POSTOPERATIVE CARE

- For ganglion and mucous cyst excisions, the hand is placed in a neutral wrist splint. Early hand elevation and early finger motion are encouraged. The splint and sutures are removed at 7 to 10 days postoperatively, and range-of-motion exercises begin at this time.
- After excision of a giant cell tumor, range-of-motion exercises should be started immediately. Sutures can be removed after 7 to 10 days.

OUTCOMES

- Ganglion cysts: The recurrence rates following open surgical excision is 21%.¹²
- Mucous cysts: Recurrence rates are as low as 2% with complete osteophyte excision at the time of surgery.²
- Giant cell tumors: Recurrence rates range from 5% to 50%.¹
 - Factors predictive of high recurrence include incomplete excision, bony invasion, type II tumors, cellularity and mitotic activity on histology, and absence of nm23 gene expression on immunohistochemistry.^{6,10}

COMPLICATIONS

- Ganglion cysts: The most common complications include wound complications (painful or hypertrophic scar, infection, neurapraxia) or early recurrence.
 - Recurrence is secondary to incomplete excision or a missed occult cyst.
 - Pain may persist postoperatively despite complete resection.
 - Stiffness can occur as a result of capsular closure or delayed postoperative movement.
- Mucous cysts: Excisions can result in extensor lag, joint stiffness, DIP joint deformity, nail plate deformity, pain, or infection.
- Giant cell tumors: In addition to recurrence, postoperative complications may include transient numbness or infection.

CHAPTER Excision of Glomus Tumors

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- Glomus tumors are benign hamartomas of the glomus body typically found in the reticular layer of the dermis in the distal phalanx or the subungual region.
- Glomus tumors account for 1% to 5% of all hand tumors.¹

ANATOMY

- The glomus body normally regulates blood flow in the reticular dermis in response to local temperature changes, functioning as an arteriovenous shunt.
- Glomus bodies are found throughout the body but are most numerous in the fingertips and the nail bed.
- Subungual involvement is found in 25% to 65% of cases, typically seen as discoloration or deformation of the nail plate.²
- Histologically, glomus cells, smooth muscles, blood vessels, and nonmyelinated nerve fibers are found within the glomus tumor. There are three distinct histologic types that can occur with the possibility of having multiple histologic tumors simultaneously.³
 - Type I: mucoid hyaline type
 - Type II: solid type (classic glomus tumor)
 - Type III: angiomatous type
- The solitary glomus tumor is a well-encapsulated lesion with numerous small lumina, most commonly found in the subungual region.
 - Multiple tumors, on the other hand, are not encapsulated and rarely subungual.

PATHOGENESIS AND NATURAL HISTORY

- Glomus tumors occur as a result of hyperplasia of the neuromyoarterial glomus body.³
- They can be solitary or multiple. Solitary tumors often present with chronic extremity pain, frequently leading to initial misdiagnosis and inappropriate treatment.¹

PATIENT HISTORY AND PHYSICAL FINDINGS

- Glomus tumors typically present in women 30 to 50 years old.
- Solitary glomus tumors have been associated with a classic triad of paroxysmal pain, pinpoint tenderness, and cold intolerance. The lesions can present with nail plate ridges, a pulp nodule, and/or bluish discoloration of the nail bed.⁴
- Often patients present with years of pain before definitive diagnosis. The tumor is often misdiagnosed because of its rarity, lack of the triad symptoms in the early course of the tumor, and several differential diagnoses.^{1,5}
- Multiple glomus tumors tend to present earlier in life than solitary glomus tumors, and are usually asymptomatic.
- Diagnostic tests include the following:
 - Love's pin test—severe pain reproduced with direct pressure
 - Hildreth's test—relief of pain with tourniquet application followed by subsequent return of pain with tourniquet release
 - Cold sensitivity test—immersion in an ice bath or application of a refrigerant spray elicits pain.

IMAGING

- If there is doubt about the diagnosis or the specific location of the tumor, MRI is helpful in identifying glomus tumors as small as 2 mm in the fingertip.
 - There will be high signal intensity on T2 images with strong enhancement following gadolinium infusion on T1 images.
 - The appearance of a high signal central dot surrounded by a zone of less signal intensity is characteristic^{3,5,6} (**FIG 1**).
- In long-standing glomus tumors, a plain x-ray may show pressure atrophy of the distal phalanx.¹
- Doppler ultrasonography can identify low signals within a hypoechogenic mass as small as 2 mm.⁶

DIFFERENTIAL DIAGNOSIS

- Leiomyoma
- Eccrine spiradenoma
- Cavernous hemangioma
- Sarcoma
- Neuroma
- Chronic paronychia
- Calcinosis
- Ganglion/mucous cyst
- Epithelial inclusion cyst

NONOPERATIVE MANAGEMENT

- Although excision is the only known cure for glomus tumors, nonsurgical treatment with prostaglandin inhibition, sclerotherapy, laser, or radiation have been described with mixed results.^{5,6}

FIG 1 • MRI of glomus tumor of the ring finger. Note the high signal intensity of the tumor.

FIG 3 • A. The tumor is palpated and marked for excision. This corresponds to the area of most tenderness on examination. **B.** The volar digital glomus tumor was resected through a zigzag incision.

SURGICAL MANAGEMENT

- A bloodless field is necessary during excision to delineate the tumor from surrounding tissues. Poor visualization increases the likelihood of inadequate resection and future recurrence (**FIG 2**).
- Subungual tumors require elevation of the nail plate and excision of the mass from the nail bed, followed by nail bed repair.
- If no gross tumor is found at exploration, remove a wedge of tissue from the area of maximum patient discomfort.⁵
- If the tumors have invaded the underlying bone, perform a partial bone excision or curettage.¹

Preoperative Planning

- Preoperative imaging, if necessary, should be performed to identify the extent of the lesion and the involvement of any local vital structures.

Positioning

- The patient is positioned supine on the operating table, and the extremity is placed on a hand table.

- The extremity is prepped and draped circumferentially.
- The appropriate anesthesia is administered (general, regional block, digital block), and a tourniquet is applied (upper arm or digit). Typically, a digital nerve block is sufficient.

FIG 2 • A clean bloodless field permits easy visualization of the glomus tumor and the surrounding normal tissue.

Approach

- The location of the lesion dictates the approach. Subungual tumors are excised through either a transungual or a midaxial incision.
- Although the transungual approach provides the best visualization, it can lead to nail bed injury and postoperative nail deformity leading to an unsatisfactory cosmetic result. Careful excision and precise placement of sutures to repair the nail bed are essential.
- The midaxial incision does not risk injury to the nail bed, but a flap needs to be developed under the periosteum, making the approach more challenging. Also, there is a risk of digital nerve injury.
- Mark the specific location of the tumor based on palpation or the area of most tenderness (**FIG 3A**).
- Volar digital tumors are resected with a zigzag incision (**FIG 3B**).

TECHNIQUES

■ Transungual Approach

- Identify the area of most tenderness or discomfort. This is particularly important in lesions that are not grossly evident on examination (**TECH FIG 1A**).
- Inject digital anesthesia and apply a tourniquet. Limit exsanguination to elevation of the extremity because the tumors lose color in a bloodless field, making it more difficult to distinguish tumor from normal surrounding

tissue.⁵

- Elevate the nail plate (**TECH FIG 1B**).
- Fold the nail over or remove it completely for adequate exposure if necessary (**TECH FIG 1C**).
- If additional exposure is necessary, make incisions over corners of the nail fold in an oblique angle to avoid contracture (**TECH FIG 1D**).
 - With a no. 15 blade, make a longitudinal incision into the nail matrix directly over the tumor. Dissect the tumor from the surrounding nail matrix.³
 - Free the lesion circumferentially to the level of the phalanx and excise it completely by leaving a defect in the nail bed (**TECH FIG 1E**).
- Curette the portion of the phalanx involved with the lesion.
- Close the nail bed defect with 6-0 plain gut suture meticulously by reapproximating the edges of the incision to minimize nail deformity (**TECH FIG 1F**).
- Replace the nail into the eponychial fold to act as a protective stent for the nail bed.
- Close the corner incisions primarily.
- Place a bulky dressing.

TECH FIG 1 • **A.** When the subungual glomus tumor cannot be palpated on examination, the area of most tenderness or discomfort is identified and marked. **B.** Elevation of the nail plate for exposure of a subungual glomus tumor. **C.** The nail is removed for exposure of the nail matrix. **D.** Incisions along the corners of the nail fold can provide additional proximal exposure if needed. **E.** The tumor is removed from a longitudinal incision in the nail matrix. **F.** Repair of the nail matrix is typically done with a 6-0 absorbable suture.

■ Lateral Approach

- This approach is more suitable for more proximal subungual lesions to avoid

violating the nail matrix.

- Make a longitudinal midaxial incision dorsal to the digital neurovascular bundle and volar to the lateral nail germinal matrix on the side of the digit closest to the lesion (**TECH FIG 2A**).
- Dissect sharply to the level of the distal phalanx.
- Create a composite dorsal subperiosteal flap with a sharp elevator. The flap consists of skin, nail, germinal tissue, and the nail plate as a unit⁷ (**TECH FIG 2B**).
- Identify the lesion and excise it or remove it with a curette. Inspect for any additional lesions to excise.
- Replace the flap and close the incision primarily with an interrupted permanent suture.
- Place a bulky dressing.

TECH FIG 2 • **A.** Incision for the lateral approach. **B.**

Exposure is obtained by raising a dorsal subperiosteal flap exposing the glomus tumor (*arrow*).

PEARLS AND PITFALLS

Approach	■ Transungual approach will give the widest view of the tumor. ■ The lateral approach has less incidence of nail deformity.
Outcomes	■ Early postoperative recurrence of symptoms is typically from an incomplete resection. ■ A delayed recurrence is likely the development of a new tumor.

POSTOPERATIVE CARE

- The patient remains in the bulky dressing for 1 to 2 weeks.
- Sutures are removed at 10 to 14 postoperative days.
- Early range of motion and return to normal activity is encouraged.

OUTCOMES

- Recurrence rates range from 15% to 24%.⁷
- Early recurrence is typically from an incomplete excision, whereas late recurrence is likely from the formation of a new tumor.

COMPLICATIONS

- A nail bed deformity is described in 3.3% to 10% of cases with transungual excision.⁷
- There is always a risk of digital nerve injury with the lateral subperiosteal approach.

73 Excision of Hemangioma of the Hand

CHAPTER

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- Hemangiomas are the most common benign tumor of infancy, with approximately 15% found on the upper extremities.^{1,2}
- The lesion is a vascular tumor consisting of plump endothelial cells with a rapid turnover and a three-phase growth cycle³:
 - Rapid cell proliferation and growth
 - Slow growth and maturation
 - Involution

ANATOMY

- Histologically, there are two types of infantile hemangiomas.
 - The capillary type is nonvascular with a spongy appearance.
 - The cavernous type has plump endothelial cells and many mast cells lining large vessels with small lumina.^{1,2}
- During the proliferative phase, the lumina widen and the endothelium flattens. As the hemangioma enters the involution phase, there is increased mast cell infiltration and progressive fibrosis of the mass.¹
- Infantile hemangiomas will stain positive for GLUT-1 in all phases, differentiating them from other hemangiomas.²

PATHOGENESIS

- Hemangiomas occur as a result of endothelial cell proliferation.
- Congenital hemangiomas are caused by a failure of proper differentiation of vascular channels during embryonic development.
- Studies have shown that children with hemangiomas have increased estrogen

levels that resolve after treatment. That, along with a female predominance, suggests a hormonal association.^{1,3}

NATURAL HISTORY

- Although only 30% of hemangiomas are visible at birth, 70% to 90% are apparent by 4 weeks of age.
- The rapid cell proliferation phase outpaces the growth of the child, whereas the slow growth phase is more proportional to the child's growth.¹
- About 50% will involute by age 5 and 90% involute by age 9 years.²
- Thirty percent of hemangiomas ulcerate with superficial bleeding.³

PATIENT HISTORY AND PHYSICAL FINDINGS

- Hemangiomas of the hand are found most commonly on the palm because it is the richest vascular area of the hand.⁴
- Superficial hemangiomas appear as a raised red papule, nodule, or plaque (**FIG 1A,B**). Deeper hemangiomas have a bluish hue (**FIG 1C**).
- An area of pallor with telangiectasias may be a precursor lesion identifiable at birth.²
- Children with a propensity to suck their fingers may present with ulcerations and paronychia.
- Other clinical findings may include pain, infection, bleeding, or congestive heart failure in very large lesions. Pain is most notable when the extremity is held in a dependent position secondary to venous engorgement.
- Platelet trapping within the hemangioma can lead to gross thrombocytopenia and consumptive coagulopathy, known as Kasabach-Merritt syndrome.
- Upper extremity growth and function is typically unaffected with hemangiomas.

FIG 1 • A,B. Superficial hemangiomas typically appear as a raised red-colored papule. **C.** Deeper hemangiomas typically have a bluish hue.

IMAGING

- Plain radiographs rarely show small, smooth, round calcifications, termed phleboliths, but otherwise are of limited value.^{4,5}
- Hemangiomas appear as a well-circumscribed mass on MRI with gadolinium enhancement.
 - The T1 signal is low and the T2 signal is high with an appearance of heterogeneity due to the variable feeding and draining vessels.¹
- Ultrasound is also a valuable preoperative tool to determine the depth of the lesion.
- Angiograms will show a well-circumscribed lesion with a blush, as well as tributary feeding and draining vessels. It can be used for diagnosis and treatment if embolization is planned.

DIFFERENTIAL DIAGNOSIS

- Arteriovenous or lymphatic malformation
- Glomus tumor
- Angiosarcoma
- Hemangioendothelioma
- Pyogenic granuloma

NONOPERATIVE MANAGEMENT

- In the absence of systemic hematologic symptoms (thrombocytopenia), the initial treatment for hemangiomas is observation.
- Other modalities including steroids, propranolol, vincristine, laser ablation, and treatment with interferon alpha have been described.
- Propranolol is thought to increase apoptosis of endothelial cells and induce adipogenesis of hemangioma stem cells.²

SURGICAL MANAGEMENT

- Surgery is rarely indicated except for cases of mass effect, uncontrollable bleeding, or lesions refractory to conservative measures.
- Presence of a pseudocapsule during the proliferative phase simplifies excision

as compared to surgery during the maturation or involution phases when the margins are more difficult to define.³

Preoperative Planning

- Appropriate radiographic studies should be performed to identify the extent of the lesion and involvement of any vital structures.
- Complete knowledge of the vascular anatomy is crucial, including assessment of the superficial palmar arch with an Allen test.

Positioning

- The patient is positioned supine on the operating table, and the extremity is positioned on a hand table.
- The extremity is prepped and draped circumferentially.
- Anesthesia is administered and a tourniquet is applied.

Approach

- The location of the lesion dictates the approach to provide adequate visualization for excision.
- Digital lesions are best approached with mid-axial or zigzag incisions, taking care to avoid crossing the flexion creases.
- Similarly, palmar lesions are best excised with zigzag incisions by avoiding placement of the incision at 90-degree angles to flexion creases.

TECHNIQUES

■ Incision and Dissection

- Apply a tourniquet without exsanguinating the extremity so that the entire tumor mass can be better identified for excision.⁴
- Make an incision to provide adequate access for excision of the hemangioma (**TECH FIG 1A,B**).
 - If ulceration is present, use an elliptical incision to excise the affected skin.
 - Take care to incise only to the depth of the dermis, avoiding the subdermal layer with any potential dilated plexuses.
- Identify the dilated subdermal vessels and ligate with suture or, if small

enough, with electrocoagulation.

- Circumferentially dissect the tumor (**TECH FIG 1C,D**).
 - Between the surrounding fat will be septal structures with capillary networks that must be identified and coagulated with bipolar cautery.
 - Any reddish or purple fat particles within the tumor should not be disturbed to avoid significant bleeding.⁶
- Carefully dissect through the subcutaneous tissue to identify and ligate the proximal and distal tributary vessels (**TECH FIG 1E**).

TECH FIG 1 • **A.** Hemangioma of the palm of the hand. Note the zigzag incision for exposure. **B.** Hemangioma of the volar thumb. The incision provides adequate exposure and does not cross the

flexion creases avoiding the risk of scar contracture. **C,D.** Identification and circumferential dissection of the tumor. Take care to avoid injury to the tributary vessels prior to ligation. **E.** The tributary vessels feeding and draining the hemangioma should be ligated as far from the tumor as possible.

■ Excision

- Identify all local neurovascular structures to confirm that the tumor is not wrapped around a nerve or vessel.
- Occasionally, the tumor may arise from vessels within striated muscle. Perform careful dissection and take a small cuff of muscle if necessary.⁴
- Excise the hemangioma and confirm that the resection is complete with margins (**TECH FIG 2A,B**).
- Inspect to confirm there is no injury to surrounding neurovascular structures (**TECH FIG 2C**).
- Release the tourniquet and obtain hemostasis.
- Perform primary closure if possible (**TECH FIG 2D**). If skin is excised due to dermal involvement and primary skin closure is not possible, the resultant defect may be closed with a skin graft or local flap.

TECH FIG 2 • A. Excision of the specimen. **B.** Resected specimen. Hemangiomas can vary in size from millimeters to multiple centimeters in size. **C.** Inspection reveals that the digital neurovascular bundle remains intact. **D.** Primary closure following excision of a thumb hemangioma.

PEARLS AND PITFALLS

Management ■ Most lesions can be managed with observation.

Operative ■ Surgical excision is easiest in the proliferative phase because of the presence of a pseudocapsule making it easier to identify tumor margins.
■ Apply the tourniquet without exsanguination.
■ Ligate the tributary vessels as far as possible from the lesion.
■ The lesion may be encasing a neurovascular structure. Meticulous dissection is crucial.

POSTOPERATIVE CARE

- A bulky dressing is applied for approximately 1 week and sutures are removed at 10 to 14 days after surgery.
- If a skin graft or flap is required, the appropriate dressing and wound care should be performed.

OUTCOMES

- Diffuse lesions have higher recurrence rates.
- Amputation may be necessary if there are multiple recurrences despite repeated excisions.
- Deep cavernous hemangiomas are the only type found to recur due to its intramuscular location, high vascularity, and proximity to neurovascular structures.⁵
- Most recurrences manifest by 2 years but can appear as long as 6 years after the primary excision.⁷

COMPLICATIONS

- Although rare, the most common complications are wound related (infection, dehiscence, contracture).
- Postoperative hematoma or bleed can best be avoided with meticulous hemostasis.

74 Excision of Metacarpal Enchondroma

CHAPTER

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- Enchondromas are benign, intramedullary, cartilaginous lesions that are the most common primary bone tumors of the hand.

ANATOMY

- Enchondromas are typically white to blue-gray solitary lesions found in the diaphysis of tubular hand bones with varying degrees of calcification.
- The lesions are most often found in medullary cavities of the metacarpals and the phalanges.

PATHOGENESIS AND NATURAL HISTORY

- Enchondromas are thought to arise from displaced chondrocytes left behind in the metaphysis and diaphysis as the epiphysis moves through the process of enchondral growth.¹
- Typically, they are found incidentally, but they can occasionally present with pathologic fractures.
- Although incidental enchondromas can be observed, those presenting with a fracture or radiographically at risk for a fracture can be treated surgically with a low likelihood for recurrence.²
- Rarely, an enchondroma may transform to chondrosarcoma.
- Malignant transformation is more likely in patients with enchondromatosis. However, malignancy occurs more often in the long bones rather than in the hand.³

PATIENT HISTORY AND PHYSICAL FINDINGS

- Enchondromas are typically asymptomatic and found incidentally.
- Bony deformities can be present with pathologic fractures.
- Patients may complain of painful swelling if bone distension is present.
- Multiple enchondromas are found in patients with Ollier disease (multiple enchondromatosis) and Maffucci syndrome (multiple enchondromatosis with multiple soft tissue hemangiomas).

IMAGING

- An appearance of a well-defined lobulated lytic lesion in the diaphysis or metadiaphysis on plains films is characteristic (**FIG 1**).
- There may be calcifications or endosteal scalloping.²
- Findings concerning for malignant degeneration include progressive cortical bone destruction, replacement of the mineralized portion by a nonmineralized component, bone proliferation, or a soft tissue mass.²

FIG 1 • Radiograph of fifth metacarpal enchondroma presenting with pathologic fracture (*arrow*).

DIFFERENTIAL DIAGNOSIS

- Chondrosarcoma
- Chondroblastoma
- Unicameral bone cyst
- Giant cell tumor of bone
- Chondromyxoid fibroma
- Fibrous dysplasia
- Bone infarct

NONOPERATIVE MANAGEMENT

- Incidental enchondromas can be observed if radiographic assessment suggests a benign, nonaggressive lesion.
- It is imperative to determine the risk of pathologic fracture, given the patient's activity level. Any concern for the possibility of pathologic fracture should prompt excision.
- The patient must be made aware of the rare but present risk of malignant degeneration with observation.
- Routine follow-up radiographs should be performed for at least a 2-year period to confirm stability of the lesion.²
- There should be a low threshold to re-evaluate a patient should symptoms develop.

SURGICAL MANAGEMENT

- Enchondromas that present with a pathologic fracture should be treated after a period of immobilization to allow fracture healing.
- If the fracture requires acute treatment with an open approach, immediate treatment of the enchondroma should be considered.⁴
- The first step in surgical management is an open biopsy with frozen section analysis to confirm the presence of cartilage tissue and rule out chondrosarcoma. If there is a concern for malignancy, the wound should be closed and further treatment deferred until permanent section analysis is performed.²
- The bony defect can be filled with bone autograft, bone allograft, a bone substitute such as calcium-based cement, or left unfilled with relatively comparable results.⁴⁻⁷

Preoperative Planning

- Radiographic imaging will reveal the location and extent of the lesion.

Positioning

- The patient is positioned supine on the operating table, and the extremity is positioned on a hand table.
- The extremity is prepped and draped circumferentially.
- The appropriate anesthesia is administered (general, regional block, digital block), and a tourniquet is applied.

Approach

- Metacarpal lesions are best approached through a dorsal incision.
- A longitudinal incision is preferable to facilitate future limb-sparing surgery if malignancy is identified on pathology.

TECHNIQUES

■ Enchondroma Excision and Bone Grafting

- Make a dorsal longitudinal incision overlying the involved metacarpal (**TECH FIG 1A**).
- Reflect the periosteum and identify the metacarpal bone (**TECH FIG 1B**).
- Create a cortical bone window with the use of a blade, rongeur, curette, or drill.
- Send a sample to pathology for frozen section to confirm the diagnosis of a benign enchondroma.
 - If there is any question of a malignancy, definitive treatment must be deferred until a final diagnosis is made on permanent pathologic analysis.
- Once diagnosis of enchondroma is confirmed, enlarge the bone window and curette the lesion (**TECH FIG 1C**).
 - It is imperative that there is adequate exposure to confirm complete excision.
- Pack the resultant cavity with preferred bone grafting material (autograft, allograft, or synthetic bone substitute; **TECH FIG 1D**).
- Confirm complete excision and adequate grafting with intraoperative

radiographs.

- Close the incision primarily (**TECH FIG 1E**).
- Apply a bulky dressing and a protective splint.

TECH FIG 1 • **A.** Dorsal longitudinal incision for a fifth metacarpal enchondroma. **B.** Soft tissue dissection reveals the periosteum of the metacarpal. **C.** An appropriately sized bone window will give access to

curettage the enchondroma specimen, which has been removed in this photo. **D.** Placement of allograft in the bone defect. **E.** Primary closure of incision.

PEARLS AND PITFALLS

Presentation	■ In cases of pathologic fracture, allow healing of the fracture site before definitive treatment because fixation of the fracture can be difficult in the thin bone surrounding the tumor. ■ If found incidentally, the lesion can be observed if no malignant features are present.
Diagnosis	■ Plain films will show characteristic features. ■ Malignancy must be ruled out before proceeding with definitive excision. Consult a pathologist in advance.
Operative	■ Make the “bone window” approximately 2/3 the size of the lesion for adequate visualization of the lesion and the cavity. ■ Confirm complete excision with imaging before leaving the operating theater.

POSTOPERATIVE CARE

- Continue protective splinting for 6 weeks after surgery but begin range-of-motion exercise at 7 to 10 days after surgery with supervised therapy.
- Obtain surveillance radiographs at 6 months, 1 year, 2 year, and subsequently if symptoms develop.

OUTCOMES

- Recurrence after curettage is between 2% and 15%.^{2,7}
- A malignant process must be considered and ruled out in all cases of recurrences, prompting a thorough review of the radiographs and histology.

COMPLICATIONS

- Enchondromas may lead to extensor tendon adhesions, nonunions, metacarpal shortening, decreased range of motion, or postoperative fracture.
- Complication rates are higher with excision of recurrent lesions.⁷

75 Excision of Peripheral Nerve Schwannoma

CHAPTER

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- Schwannomas, also termed neurilemmomas are the most common benign nerve tumors of the hand.
- The lesions are peripheral nerve sheath tumors arising from Schwann cells within the endoneurial layer.
- Schwannomas do not result in neural dysfunction. As a result, if it is not considered in the differential for an upper extremity mass, inadvertent nerve injury may result during excision.

ANATOMY

- Schwannomas grow eccentrically from the nerve sheath and are well encapsulated. As a result, nerve fasciculi cannot enter the lesions.
- The tumors are typically found on the volar surface of the forearm or the hand and are usually less than 2.5 cm in diameter.¹
- On histology, there are interlacing fascicles of spindle cells with large oval nuclei in a palisade appearance, referred to as Antoni type A. Areas that are less well defined with fewer cells and less extracellular ground substance are termed Antoni type B.^{1,2}

PATHOGENESIS

- Schwannomas are a result of a benign proliferation of differentiated Schwann cells of a single nerve funiculus that surround the nerve.³
- Malignant transformation is rare.⁴
- Neurofibromas also arise from Schwann cells but can easily be differentiated from schwannomas due to growth within the substance of the nerve, making

enucleation impossible.

NATURAL HISTORY

- Schwannomas are quite rare and have a variable presentation, frequently leading to an incorrect clinical diagnosis.
- Multiple schwannomas of the large peripheral nerve trunks may be found in patients with neurofibromatosis type 1 (von Recklinghausen disease).
- Patients with neurofibromatosis type 2 develop bilateral acoustic schwannomas.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Schwannoma typically presents in the middle decades of life as a well-circumscribed, firm, painless, slow growing tumor. It is rarely associated with a neurologic deficit.
- Typically, schwannoma is a mass that appears in line with the nerve trunk. Therefore, it is mobile in the transverse direction but not in the longitudinal plane.²
- Although schwannomas are usually solitary, they have been found to occur as multiple lesions. These tumors usually have no mass effect or ischemic effect of the involved nerve.⁵
- On exam, it can appear to have a cystic consistency often being misdiagnosed as a ganglion.^{3,5}
- Intraoperatively, the tumor can easily be shelled out, distinguishing it from other nerve tumors (**FIG 1A**).
- Schwannomas appear within the digital nerve approximately half the time. However, it is uncommon to find one distal to the proximal interphalangeal joint of the fingers or distal to the interphalangeal joint of the thumb (**FIG 1B**).³

FIG 1 • A. Schwannomas are well-circumscribed tumors that can easily be enucleated from the involved nerve. **B.** Approximately half of schwannomas are found within digital nerves.

FIG 2 • MR images of an ulnar nerve schwannoma. **A.** T2-weighted image with bright appearance of the schwannoma. **B.** T1-weighted image has an intermediate signal intensity due to the presence of fat within the tumor.

IMAGING

- MRI is the standard to localize the tumor and delineate the surrounding anatomy for surgical planning.
- The lesion appears bright on T2-weighted images though the presence of adipose tissue within the lesion will give an intermediate signal intensity on T1-weighted images (**FIG 2**).
- The similar appearance on MRI makes it difficult to distinguish between a schwannoma, neurofibroma, and a malignant nerve sheath tumor.
- High-frequency ultrasound will show schwannomas as masses of low echogenicity with distal enhancement.²

DIFFERENTIAL DIAGNOSIS

- Ganglion cyst
- Neurofibroma
- Giant cell tumor
- Lipoma
- Epidermal inclusion cyst

NONOPERATIVE MANAGEMENT

- For asymptomatic schwannomas, observation is acceptable.
- Any malignant features on MRI imaging should prompt a discussion with the patient for surgical excision.

SURGICAL MANAGEMENT

- Surgery is indicated for definitive diagnosis, for symptom control, or to exclude malignancy.
- An excisional biopsy is performed by enucleation of the tumor following an intraneural dissection.
- Schwannomas are noninfiltrative and can be freed from adjacent fascicles without injury.³
- If the tumor is adherent to the surrounding tissue or is not well encapsulated, the diagnosis should be questioned.
 - An incisional biopsy should be performed with definitive treatment delayed until after a permanent pathologic examination.¹

Preoperative Planning

- Preoperative imaging, typically MRI, can be used to identify the extent of the lesion and its proximity to other vital structures.

- The possibility of postoperative neurologic deficit, though uncommon, must be discussed with the patient.

Positioning

- The patient is positioned supine on the operating table, and the extremity is positioned on a hand table.
- The extremity is prepped and draped circumferentially.
- The appropriate anesthesia is administered (general, regional block, digital block) and a tourniquet is applied.

Approach

- The location of the lesion dictates the technique and the approach chosen.
 - Palmar lesions are best approached with a zigzag incision.
 - A midaxial approach is most effective for digital nerve lesions for best visualization and protection of the adjacent digital vessel.
 - Median nerve lesions should be excised with an open carpal tunnel incision.

TECHNIQUES

■ Schwannoma Enucleation

- Expose the involved nerve and its nerve fascicles proximal and distal to the tumor. Fascicles will be seen draping over the mass and may have a multilobulated or pedicled appearance.
- Completely inspect the nerve to determine the location where there is a splaying of fascicles that would be the best resection plane (**TECH FIG 1A**).
- Incise the nerve sheath longitudinally, taking care to avoid injury to the fascicles and vessels running within the epineurium.
- Carefully peel away the fascicles from the tumor circumferentially until the tumor can be shelled out from the nerve (**TECH FIG 1B**).
- Following resection, inspect the nerve to confirm fascicular continuity (**TECH FIG 1C**).
- In cases of digital nerve, an operating microscope is needed to preserve axons.
 - Identify normal nerve fibers proximally.

- Trace axon bundles distally and carefully dissect them free from the mass.
- The specimen should have no nerve fascicles within it (**TECH FIG 1D**).
- Close the incision with interrupted 4-0 nylon sutures and place a bulky dressing.

TECH FIG 1 • Schwannoma of the ulnar nerve. **A.**

Splicing of the nerve fascicles around the lesion. A clean plane exists between the mass and the fascicles. **B.** The mass is shelled out carefully between the spliced fascicles. **C.** Following resection of the schwannoma, all nerve fascicles remain intact. **D.** Schwannoma specimen.

PEARLS AND PITFALLS

Indications	■ Diagnosis—exclude malignancy ■ Symptom control
Diagnosis	■ Misdiagnosis is common—often confused with a ganglion. ■ MRI is the best imaging modality.
Surgical approach	■ Loupe magnification or an operative microscope will facilitate microdissection to minimize axonal injury. ■ If the mass is adherent to the nerve, question the preoperative diagnosis and consider malignancy.

POSTOPERATIVE CARE

- A bulky dressing is typically adequate. Early hand elevation and early finger motion are encouraged.
- The sutures are removed at approximately 10 days and range-of-motion exercises begin at this time.

OUTCOMES

- Recurrence is very rare.
- Transient paresthesias are common, but long-term nerve dysfunction is very uncommon.

COMPLICATIONS

- Incidence of postoperative neurologic deficit is 4%.⁴
- Inadvertent nerve resection can occur if the diagnosis is not considered preoperatively.

76 Excision of Malignant Skin Tumors

CHAPTER

Paymon Rahgozar and Kevin C. Chung

DEFINITION

- Basal cell carcinoma (BCC), the second most common cutaneous malignancy of the hand, arises from the basal layer of the epithelium or from the external root sheath of the hair follicle.
- Squamous cell carcinoma (SCC) is the most common malignant cutaneous tumor of the hand.
- Melanomas are aggressive tumors of the epidermis that account for 3% of all hand tumors.
- Both SCC and melanoma can invade locally, involve regional lymph nodes, or metastasize to distant sites.

ANATOMY

- BCCs most often occur in sites with higher concentrations of pilosebaceous follicles.
 - Up to 87% of the tumors appear on the dorsum of the hand between the wrist crease and the metacarpal heads.¹
- SCC derives from the epidermal keratinocyte cell layer but can also develop in the nail matrix.
 - Although dorsal hand involvement is common for SCC, the tumors can also be found on the nails, fingers, interdigital skin, or dorsal wrist with relative frequency.^{1,2}
- Melanoma is from a neural crest origin developing from the dendritic cell within the epidermis. The melanocytes can migrate to both cutaneous and noncutaneous locations, such as the nail matrix.
 - Subtypes include superficial spreading (most common), nodular (most

aggressive), lentigo maligna, acral lentiginous, and amelanotic melanoma.

- Skin tumors found in the palm are most commonly the acral lentiginous subtype.^{1,3}

PATHOGENESIS

- Malignant tumors of the hand are rare, often leading to a delay in diagnosis and treatment.
- Risk factors for malignant skin tumors are similar and include sun/ultraviolet exposure, fair skin, male gender, or advancing age.
- Although basal cell cancer is the most common cutaneous malignancy, only 2% to 3% of all BCC appear in the upper extremities.² Therefore, in the hand, squamous cell cancer is the most common cutaneous malignancy.
- A history of severe burns, chronic ulcers, or immune compromise can lead to SCC.
- Those with a personal history of skin cancer, family history of melanoma, history of a changing mole, or exposure to coal tar, arsenic compounds, or radiation have an increased risk of melanoma.

NATURAL HISTORY

- Basal cell carcinoma
 - In comparison to SCC or melanoma, BCC does not arise from malignant changes of pre-existing structures. It originates from the basal layer of the epithelium or the root sheath of a hair follicle.²
 - High-risk lesions include the superficial, micronodular, morpheaform, and infiltrative subtypes.³ Nodular BCC is the most common low-risk subtype.
 - The metastatic rates in BCC are as low as 0.1%, presumably because the reticular dermis functions as a relative barrier to its spread.^{2,4}
- Squamous cell carcinoma
 - Seventy-five percent of skin cancers that appear in the hand are SCC with a male-to-female ratio of 4:1.⁵
 - SCCs originate from the spindle cell layer of the epithelium.² The tumor will typically begin as a nodule and will progress to develop areas of necrosis.
 - High-risk lesions are those with a diameter greater than 2 cm, vertical depth greater than 4 mm, rapid growth, perineural invasion, or presence of poorly differentiated cells.^{4,5}
 - The risk of metastases involving the extremities is 2% to 5%.⁶
- Melanoma

- The incidence of melanoma is increasing at a rapid rate, nearly doubling every 8 to 10 years.^{3,6}
- The lifetime probability of developing melanoma is 1 in 49 for males and 1 in 73 for females.
- Prognosis is dependent on the vertical thickness (Breslow classification) or the anatomic level of invasion (Clark classification).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Basal cell carcinoma
 - BCCs are characteristically found in middle-aged and elderly light-skinned individuals who report a history of multiple skin malignancies.
 - The typical appearance is that of a raised maculopapular lesion in the setting of skin atrophy, skin discoloration, and telangiectasias, with raised pearly borders and eventual ulceration (**FIG 1A**).
- Squamous cell carcinoma
 - SCC may appear as a slow-growing, verrucous, exophytic lesion or as a rapid-growing, nodular, indurated lesion with raised borders and early ulceration (**FIG 1B**).
 - The slow-growing variety has a higher propensity to metastasize.

FIG 1 • A. Basal cell carcinoma on the dorsum of the hand. Note the raised pearly borders. **B.** Squamous cell carcinoma of the dorsum of the hand with ulceration. **C.** Squamous cell carcinoma with nail involvement. Often, this is misdiagnosed as a chronic paronychia or other benign pathology. **D.** Subungual melanoma with a Hutchinson sign, extension of pigment from the nail bed to the proximal nail fold.

- With time, most untreated SCCs will eventually become an inflamed, indurated lesion with central ulceration.
- The frequency of lesions on the dorsum of the hand is consistent with its association with sun exposure.
- It can be distinguished from basal cell cancer by the lack of a well-defined edge when placing stretch on the tumor with two hands.⁵

- Involvement of the nail unit presents as a chronic ulcer and is often misdiagnosed as a chronic paronychia, pyogenic granuloma, or verruca vulgaris⁵ (**FIG 1C**).
- Similar to melanoma, regional lymph nodes should be evaluated to evaluate for lymphadenopathy.
- Melanoma
 - Evaluation involves the ABCs (asymmetry, borders, color) with regard to a changing mole.
 - Critical findings include asymmetry, irregularity, diameter greater than 6 mm, or presence of satellite lesions.
 - Regional lymph nodes must be examined to evaluate for metastasis.
 - Subungual melanoma may present with a Hutchinson sign (extension of brown/black pigment from the nail bed onto the cuticle or nail fold) (**FIG 1D**). It can also appear as a pigmented streak of the nail bed that is wider than 3 mm.

IMAGING

- Plain films can reveal bony involvement, particularly with nail bed involvement.
- Other imaging studies are typically performed to rule out distant disease (CT, PET, MRI).

DIFFERENTIAL DIAGNOSIS

- Hemangioma
- Dermatofibroma
- Blue nevus
- Seborrheic keratosis
- Kaposi sarcoma
- Metastasis
- Subungual lesions: chronic paronychia, pyogenic granuloma, onychomycosis, glomus tumor, hematoma

NONOPERATIVE MANAGEMENT

- Basal cell carcinoma
 - Small or superficial lesions can be considered for treatment with electrodesiccation and curettage, cryotherapy, radiotherapy, or CO₂ laser.
 - Nonoperative management is contraindicated in morpheaform or sclerosing

subtypes.

- Squamous cell carcinoma
 - Small, low-risk, or in situ squamous cell lesions can be managed conservatively in patients who are high-risk operative candidates with electrodesiccation and curettage, cryosurgery, or 5-FU.
 - Radiation therapy may also be used to treat inoperable lesions or recurrences.
- Melanoma
 - There is no role for nonoperative management in melanoma.

SURGICAL MANAGEMENT

- Basal cell carcinoma
 - Small (no more than 2 cm) BCCs should be resected with at least 4-mm margins.
 - Large (over 2 cm) BCCs or those with high-grade features require a 6-mm margin or the use of Mohs micrographic surgery to maximize preservation of uninvolved tissue.
 - Mohs micrographic surgery should be applied in the setting of tumors with aggressive malignant features and for morpheaform or sclerosing subtypes.²
- Squamous cell carcinoma
 - Because of the more aggressive nature of SCC, a wider margin of resection is typically necessary as compared to BCC.
 - A 3- to 10-mm margin of disease-free tissue should be maintained.
 - Mohs micrographic excision results in the highest cure rate and the best preservation of uninvolved tissue. It should be performed for high-risk lesions.
 - If the nail matrix is involved, amputation at the DIP joint is necessary.
- Melanoma
 - The depth of the lesion (Breslow thickness) dictates margin of resection:
 - In situ tumors: 0.5-cm margin
 - Less than 1 mm deep: 1-cm margin
 - 1 to 4 mm deep: 2-cm margin
 - More than 4 mm deep: 2- to 3-cm margin
 - For melanomas deeper than 0.76 mm, treatment includes intraoperative lymph node mapping with sentinel lymph node biopsy, followed by completion of lymphadenectomy if positive.
 - For nail matrix melanomas, the digit should be amputated proximal to the

DIP joint.

- In proximal digital melanomas with perineural invasion or bone involvement, a complete digital amputation or ray amputation is typically necessary.
- Large excision reconstruction can involve primary closure, skin graft, locoregional flap, or free flap (**FIGS 2** and **3C**).

Preoperative Planning

- Preoperative imaging, if necessary, should be performed to identify the extent of the lesion and the involvement of any vital structures.
- In cases of malignancy, the extremity should not be exsanguinated with the use of an Esmarch bandage to avoid a theoretical risk of seeding malignant cells.

Positioning

- The patient is positioned supine on the operating table, and the extremity is positioned on a hand table.
- The extremity is prepped and draped circumferentially, including the axilla if sentinel lymph node biopsy is planned.
- The appropriate anesthesia is administered (general, regional block, digital block), and an appropriate tourniquet is applied (upper arm or digit).

Approach

- The location of the lesion dictates the technique and the approach chosen.
- Wide local excision involves excision of the lesion with a predetermined perimeter of normal tissue (**FIG 3A**).
 - It is important to mark the specimen to orient the pathologist (**FIG 3B**).
 - If any margins are positive, the pathology will dictate the location for repeat excision.
- To facilitate primary closure, if the anatomy and the size of the lesion permit, the excision should be an ellipse.
- The incision for a biopsy should be designed longitudinally so that the biopsy site can be resected at the time of definitive treatment.
- Mohs micrographic surgery has good results for BCC and SCC. A Mohs-trained surgeon can excise the lesion and perform immediate pathologic analysis for critical areas where tissue preservation is important.

FIG 2 • SCC excision requiring a local flap for closure. **A.** Preoperative markings for a rhomboid flap for reconstruction. **B.** Closure after advancement of the flap.

FIG 3 • Wide local excision of a SCC. **A.** The inner circle represents the boundaries of the lesion and the outer circle is the excision of a margin of normal tissue. **B.** The specimen is marked with sutures for pathologic orientation. **C.** Closure of dorsal hand defect with a split-thickness skin graft.

TECHNIQUES

■ Mohs Micrographic Surgery

- Remove all evidence of gross tumor.
- Excise a thin 2- to 3-mm margin with the tissue (**TECH FIG 1A**). Bevel the peripheral skin edge such that it is in the same horizontal plane as the deep margin.

- Using a color-coded three-dimensional orientation, map the tissue for reference (**TECH FIG 1B**).
- Examine the deep and peripheral margin by frozen section analysis to determine the precise anatomic location of any residual tumor (**TECH FIG 1C**).
- Re-excise any residual tumor and repeat pathologic evaluation until margins are negative (**TECH FIG 1D-F**).

TECH FIG 1 • Mohs micrographic surgery. **A.** Gross tumor with a thin margin is excised. **B.** The sample is divided and mapped with color to help pinpoint any areas of residual tumor with frozen section analysis. **C.** Microscopic evaluation reveals that there is residual tumor in segment 4. **D–F.** The process is repeated, focusing on re-excision of the involved quadrant until all clear margins are obtained.

Incision	■ Be certain of diagnosis before committing to a transverse incision for resection. This will make a limb-sparing incision more challenging for definitive resection if the lesion is malignant.
Basal cell carcinoma	■ Telangiectasias with raised pearly borders are characteristic.
Melanoma	■ Always consider amelanotic melanoma as part of the differential of a nonpigmented skin lesion. ■ Before committing to a definitive reconstruction, perform temporary coverage until the final pathology confirms negative margins. ■ Sentinel lymph node biopsy is often part of the management algorithm.
Squamous cell carcinoma	■ Biopsy tissue in a chronic or nonhealing skin or nail matrix lesion
Mohs micrographic surgery	■ Very low recurrence rates for BCC and SCC

POSTOPERATIVE CARE

- The hand is placed in a bulky dressing from the proximal forearm to the MP joints. Early hand elevation and early finger motion are encouraged.
- The splint and sutures are removed at 1 week, and range-of-motion exercises begin at this time.
- In cases of melanoma, the patient should follow up at regular 3-month intervals for 2 years, 6-month intervals for the following 2 years, and annually thereafter.

OUTCOMES

- Basal cell carcinoma
 - Cure rates for primary BCC treated with Mohs surgery have been reported as high as 99%.²
 - Recurrence rates are higher for lesions with increasing size or for those with more aggressive clinical subtypes.
- Squamous cell carcinoma
 - The risk of metastasis and recurrence is higher on the upper extremity than

SCC at other locations on the body.

- Excision with Mohs micrographic surgery has recurrence rates as low as 2.4%. However, periungual lesions have comparatively higher recurrence rates.⁴
- The histologic risk factors associated with recurrence include degree of cellular differentiation, depth of tumor invasion, and presence of perineural invasion.²
- Melanoma
 - Prognosis is dependent on depth of tumor invasion, presence of nodal disease, and presence of metastatic disease.
 - The approximate 5-year survival rate for a melanoma less than 0.76 mm thick is 98%. Survival drops to 30% with nodal involvement and less than 10% if there are metastases.⁶

COMPLICATIONS

- Incomplete resection on final pathology warrants re-excision.
- With lymphadenectomy, there is a risk of hematoma, seroma, lymphocele, or lymphedema. Although the risk is also present with sentinel lymph node biopsies, it is much less commonly encountered.

PART 7

Lower Limb Reconstruction and Amputation

Section I: Anesthesia and Emergency Procedures

1 **Femoral and Adductor Canal Blocks**

CHAPTER

Sarah Madison and Jean-Louis Horn

DEFINITION

- A peripheral nerve block is an analgesic technique in which local anesthetics are injected percutaneously in proximity to a sensory nerve.
- The location of the injection determines the distribution of analgesia.
- Femoral nerve block may be used for postoperative analgesia for procedures on the anterior thigh, knee, medial leg, or medial ankle.
- Adductor canal block may be used for postoperative analgesia for procedures on the knee or medial leg.
- A continuous infusion of local anesthetic via a perineural catheter can provide analgesia for several days after surgery.
- Nerve blocks are often part of a multimodal regimen that also includes systemic medications.
- Nerve blocks can reduce pain and opioid consumption and enhance satisfaction and recovery.¹
- Depending on the location and extent of surgery, nerve blocks may be used for surgical anesthesia.

ANATOMY

- The femoral nerve arises from the lumbar plexus and is formed by the ventral rami of L2-L4.
- In the area of the femoral triangle, the femoral nerve lies deep to the fascia

iliaca, lateral to the femoral artery, and superficial to the iliacus muscle.

- The femoral nerve divides into anterior and posterior divisions and descends as the saphenous nerve to the medial leg.
- The posterior branch provides motor innervation to the quadriceps muscles as well as sensory articular branches to the knee joint.
- The saphenous nerve, obturator nerve (posterior division), and the nerve to the vastus medialis lie within the adductor canal.
- The adductor canal is bounded by the sartorius and the vasto-adductor membrane medially, the vastus medialis anteriorly, and adductor longus and magnus muscles posteriorly.
- The adductor canal also contains the femoral artery and vein.
- The saphenous nerve and the nerve to the vastus medialis supply sensory branches to the knee.²

PATIENT HISTORY AND PHYSICAL FINDINGS

- A preoperative history and physical must be performed prior to any anesthetic technique.
- A thorough history and physical exam will include anesthetic history, exercise tolerance, cardiopulmonary examination, and airway examination.
- Any pre-existing neuropathies in the distribution of the block should be defined and documented.
- Any local infections, masses, previous surgeries, or other irregularities at the site of injection should be identified.

IMAGING

- Ultrasound imaging confers efficiency and increases the success rate of most peripheral nerve blocks.
- Using a high-frequency linear transducer, scan in a transverse orientation at the level of the inguinal crease. The femoral artery and femoral nerve should be easily identified in cross-section (**FIG 1**).
- The adductor canal block is often performed in a location that is proximal to the true adductor canal, near the point at which the sartorius muscle covers the femoral vessels. The nerve can be visualized next to the femoral artery, just deep to the sartorius muscle (**FIG 2**).

NONOPERATIVE MANAGEMENT

- The balance of risks and benefits must be considered before any nerve block.

Sometimes, it is more appropriate to only employ systemic medications for pain control.

- Opioids and nonopioid adjuvant medications may be used when medically appropriate, with or without a nerve block.

SURGICAL MANAGEMENT

- Femoral nerve block is indicated for postoperative analgesia of the anterior thigh, knee, medial leg, or medial ankle, or for surgical anesthesia of the anterior thigh.
- When combined with a sciatic block, it can be used for surgical anesthesia of the foot/ankle.
- Local anesthetics will affect both motor and sensory nerves. Blocking the femoral nerve at the level of the inguinal crease results in quadriceps weakness.
- Adductor canal block is indicated for postoperative analgesia of the knee, medial leg, or medial ankle.
- It can be used as a surgical anesthetic in conjunction with a sciatic block for procedures on the foot/ankle.

FIG 1 • Ultrasound image of femoral nerve block. FN, femoral nerve; A, femoral artery.

FIG 2 • Ultrasound image of adductor canal block. SN, saphenous nerve; SM, sartorius muscle; A, femoral artery; V, femoral vein.

- A nerve block in the adductor canal is less likely to cause quadriceps weakness than a femoral nerve block; however, local anesthetic may spread proximally and affect motor nerves.
- The nerve to the vastus medialis is reliably anesthetized with an adductor canal block, but the overall effect on quadriceps function is minimal.³

Preoperative Planning

- Surgical site, extent of incision, anticipated degree of pain, and any pre-existing conditions that increase risk of complications should be considered before offering the patient a nerve block.
- Postoperative ambulatory status should be determined to optimize dosing.
- Crutch training, if appropriate, should take place prior to surgery.
- Inpatients should be labeled as a “fall risk” and should not get out of bed without assistance.
- Femoral nerve blocks for outpatients should be carefully considered and only performed with close follow-up and an otherwise low risk of falls.
- The use of crutches and a knee immobilizer may attenuate fall risk with ambulation after a femoral nerve block.

Positioning

- The patient should be positioned supine with the operative leg slightly externally rotated.

- The bed should be flat with hips extended.
- The patient's ipsilateral hand may be kept out of the sterile field by lightly taping it to the chest.
- The operator should stand on the side to be blocked, with the ultrasound machine on the other side of the patient.

Approach

- With the use of ultrasound, the nerve may be approached either in-plane (needle parallel to transducer surface) or out-of-plane (needle perpendicular to transducer surface) with the ultrasound probe placed in a transverse orientation.
- When a nerve stimulator technique is used, the needle approach is generally *with* the long axis of the nerve, at a 45-degree angle to the skin.

TECHNIQUES

■ Femoral Block: Ultrasound-Guided Technique

- Position the patient as described above, with ASA (American Society of Anesthesiologists) standard monitors and supplemental oxygen applied.
- IV sedation, usually with fentanyl and midazolam, may be titrated to patient comfort.
- Using a high-frequency linear transducer, scan at the level of the inguinal crease in a transverse orientation to visualize the femoral artery and nerve in cross-section.
 - The best image may be obtained in a location proximal to the bifurcation of the femoral artery where the neurovascular bundle is closest to the skin.
 - Identify the fascia lata, fascia iliaca, femoral nerve, and iliacus muscle.
 - Slowly tilt the ultrasound transducer to optimize nerve imaging.
- Estimate the depth of the nerve in the ultrasound image.
- After sterile skin preparation, place a skin wheal just lateral to the ultrasound probe.
 - The depth of the nerve should guide the insertion site; start closer to the probe for more superficial targets, and farther away if the target is deeper.
- Insert the block needle in the plane of the ultrasound image, visualizing the tip of the needle in real-time as the target is approached (**TECH FIG 1**).

- The needle should pass through the fascia iliaca just lateral to the nerve.
- Tactile feedback through the needle may include a “pop” as the needle traverses fascial layers.

TECH FIG 1 • Positioning and approach for ultrasound-guided in-plane femoral nerve block.

- Take care to avoid the lateral edge of the nerve. The patient may experience a paresthesia if the nerve is contacted directly.
- The lateral circumflex femoral artery or one of its branches may be in the needle path or pass through the nerve, and should be avoided.
- After careful aspiration, inject a small amount of local anesthetic.
- Local anesthetic spread should appear as hypoechoic fluid filling the space deep to fascia iliaca and surrounding the nerve.
- The needle may be advanced closer to the nerve as a local anesthetic pocket is formed (hydrodissection); this reduces the risk of needle-nerve contact.
- When the needle is positioned in close proximity to the nerve, and local anesthetic spread is confirmed around the nerve, an additional 10 to 15 mL of local anesthetic can be injected.
- Local anesthetic selection and volume of injection depend on the goals of the block.
 - For a surgical block, use 20 to 30 mL of 1.5% mepivacaine, 2% lidocaine, 0.5% bupivacaine, or 0.5% ropivacaine.
 - For an analgesic block, use 15 to 20 mL of 0.25% bupivacaine or 0.25% ropivacaine.

- A catheter may be placed for continuous local anesthetic infusion.
 - Use 0.2% ropivacaine or 0.125% of bupivacaine at 4 to 6 mL/h for continuous infusion, with a patient-controlled bolus of 2 to 4 mL every 30 minutes.
 - Infusions are generally continued for 2 to 3 days following surgery.
-

■ Femoral Block: Nerve Stimulator Technique

- Following patient positioning and preparation described above, identify and mark the inguinal crease.
- Standing near the patient's hip and facing the head, palpate the femoral pulse along the crease.
- After sterile prep, place a local anesthetic skin wheal 2 cm lateral to the femoral artery pulse.
- Insert a stimulating block needle at a 45 to 60 degree angle to the skin in a cephalad direction (**TECH FIG 2**).
 - A quadriceps twitch ("patellar snap") should be elicited at a current of 0.2 to 0.5 mA. Redirect the needle until the appropriate stimulation is observed.
 - Sartorius contraction indicates a needle placement on the anterior division of the femoral nerve. Further advancement of the needle toward the posterior division of the nerve will usually solve this.
 - Aspiration of blood indicates intravascular placement. Reposition the needle.
 - Muscle contraction at a current of greater than 0.5 mA usually indicates inadequate needle-nerve proximity and may result in an incomplete or failed block.

TECH FIG 2 • Positioning and approach for stimulator-guided femoral nerve block.

- Muscle contraction at a current of less than 0.2 mA may indicate intraneural needle placement. Withdraw the needle slightly before injecting, carefully noting injection pressure.
- Avoid high-pressure injection (greater than 15 psi), indicative of an intraneural needle placement.
- Once an acceptable motor response is elicited, inject local anesthetic as above. The motor response should terminate with injection (Raj test).

■ Adductor Canal Block: Ultrasound-Guided Technique

- Position and prepare the patient as for a femoral block. Externally rotating the leg may facilitate access to the adductor canal.
- Place a high-frequency linear transducer in a transverse orientation over the medial thigh at the midpoint between ASIS and the superior pole of the patella.
 - Identify the sartorius, vastus medialis, and adductor longus muscles.
 - The femoral artery and vein lie within the adductor canal.
 - The saphenous nerve may be visualized just lateral to the artery, beneath the sartorius muscle and the vasto-adductor membrane.
- Estimate the depth of the nerve in the ultrasound image.
- After sterile skin preparation, place a skin wheal just lateral to the ultrasound probe.

- The depth of the nerve should guide the insertion site.
- Insert the block needle in the plane of the ultrasound image, visualizing the tip of the needle in real-time as the target is approached (**TECH FIG 3**).
- Traverse the sartorius muscle to position the needle tip just lateral to the femoral artery.
- A “pop” may be felt as the needle passes through fascial layers.

TECH FIG 3 • Positioning and approach for ultrasound-guided adductor canal block.

- Take care to avoid the femoral vein, which often lies deep and lateral to the artery, and may not be visible when pressure is applied to the ultrasound transducer.
- After careful aspiration, inject a small amount of local anesthetic.
 - Observe local anesthetic spread in the ultrasound image. This should appear as hypoechoic fluid filling the space deep to sartorius and lateral to femoral artery.
 - Ensure that local anesthetic is not tracking back along the sartorius muscle, but rather staying contained in the adductor canal while partially surrounding the femoral artery.
 - The needle should be advanced beyond the subsartorial fascia.
 - When the needle is positioned in close proximity to the nerve, and local anesthetic spread is confirmed around the nerve, an additional 10 to 15 mL of local anesthetic can be injected.
- The adductor canal block can be used as an analgesic block or as a surgical block in combination with sciatic block for surgery below the knee.

- For a surgical block, use 15 to 20 mL of 1.5% mepivacaine, 2% lidocaine, 0.5% bupivacaine, or 0.5% ropivacaine.
- For an analgesic block, use 10 to 15 mL of 0.25% bupivacaine or 0.25% ropivacaine.
- A catheter may be placed for continuous local anesthetic infusion.
 - Use 0.2% ropivacaine or 0.125% bupivacaine at 4 to 6 mL/h for continuous infusion, with a patient-controlled bolus of 2 to 4 mL every 30 minutes.
 - Infusions are generally continued for 2 to 3 days following surgery.

PEARLS AND PITFALLS

Positioning	■ In obese patients, retracting and taping the abdominal pannus helps optimize ultrasound imaging.
Sterility	■ For catheter placement, nerve blocks should be performed under strict sterile conditions.
Paresthesias	■ Avoid needle-to-nerve contact if possible. Use hydrodissection to achieve proper needle placement.
Vascular puncture	■ The femoral and adductor canal blocks involve needle placement in close proximity to vascular structures. To avoid vascular puncture, always visualize the needle tip in the ultrasound image while advancing.
Local anesthetic toxicity	■ Even with acceptable needle visualization, vascular puncture can occur. Always aspirate before injection, inject slowly, and visualize local anesthetic spread in the ultrasound image. Epinephrine may be used at a low concentration (1:400 000) as a vascular marker. Do not exceed the maximum safe dose of local anesthetics.
Catheter placement	■ Once a catheter is placed, its position should be confirmed with ultrasound imaging. Inject a small volume of local anesthetic through the catheter to ensure appropriate spread around the nerve.
Dressing	■ Catheters should be secured with a clear occlusive dressing. An anchoring device may be used as well and should be secured away from the surgical field or tourniquet site.
Block assessment	■ Quadriceps weakness is an early sign of successful femoral nerve block. Femoral and adductor canal nerve blocks are reliably assessed with testing the skin over the medial malleolus.

POSTOPERATIVE CARE

- Following a nerve block procedure, patients should be monitored for at least 30 minutes for any signs of local anesthetic toxicity.
- Patients should be contacted every day until the block wears off or the catheter is removed.
- Leakage from the catheter site is normal and expected but can be minimized with the application of surgical glue at the insertion site.
- Patients should be educated on expected weakness and fall risk.
 - Crutches and a knee immobilizer should be provided when appropriate.
 - Careful consideration should be given to using continuous femoral blocks for outpatients.
- Patients should be encouraged to use their systemic analgesics as needed.
 - Perioperative use of multimodal analgesia may include acetaminophen, NSAIDs, and/or gabapentinoids around the clock to improve pain management and decrease opioid usage.
 - Systemic analgesics should be initiated prior to the block wearing off.
- Dressings should be left alone until the catheter is removed.
 - Dressing changes are not necessary and may increase the risk of infection or catheter dislodgement.

OUTCOMES

- Peripheral nerve blocks provide better pain control than traditional medications; they reduce opioid consumption and its associated side effects.
- Patient satisfaction is higher when peripheral nerve blocks are used for perioperative pain control.
- Pain management strategies that include a peripheral nerve block may reduce the systemic inflammatory response and reduce persistent pain that is associated with surgery.⁴

COMPLICATIONS

- Peripheral nerve blocks have a low complication rate.
- Short-term complications may include prolonged numbness, weakness, or paresthesias.
- Long-term numbness, weakness, or paresthesias are rare.
 - In a multicenter, international clinical registry of regional anesthetics, the all-cause 60-day rate of neurological sequelae is 8.3/10 000.⁵

- Local anesthetic systemic toxicity (LAST) is a rare but potentially deadly complication.
- A LAST protocol should be in place in institutions where nerve blocks are performed.
 - LAST checklist and resuscitation guidelines should be posted in the block area (https://www.asra.com/content/documents/asra_last_checklist.2011.pdf).
 - Resuscitation medications (including Intralipid) and equipment should be available in the block area.
 - Access to cardiopulmonary bypass should be available in case of refractory cardiovascular collapse.

CHAPTER Popliteal Nerve Blocks

Ming Zhuo-Stine and Sarah J. Madison

DEFINITION

- The popliteal nerve block targets the sciatic nerve in the popliteal fossa proximal to its bifurcation into the common peroneal and tibial nerves.
- It is a commonly used block for surgeries involving the lower leg, ankle, and foot.
- The nerve block can provide surgical anesthesia or postoperative analgesia. The duration of the block varies based on the choice of local anesthetic and the choice of single injection versus continuous catheter technique. For painful surgeries, the continuous catheter technique can provide several days of excellent postoperative pain control.¹
- The popliteal nerve block spares the medial aspect of the lower leg, an area that is innervated by the saphenous nerve. A femoral or saphenous nerve block must be performed in conjunction with a popliteal block for full sensory blockade of the lower leg (**FIG 1**).

FIG 1 • Sensory distribution of the leg.

ANATOMY

- The sciatic nerve consists of two distinct nerves, the tibial and common peroneal nerves, which provide motor and sensory innervation to the majority of the lower leg. The two nerves have their own epineurium and are encased in an additional layer of connective tissue.^{2,3}
- Within the popliteal fossa, the branches of the sciatic nerve usually lie lateral and posterior to the popliteal vessels. More proximally, the nerve can be found between the biceps femoris, and semitendinosus and semimembranosus tendons.
- 2 to 10 cm proximal to the popliteal fossa crease, the sciatic nerve bifurcates into the tibial and common peroneal nerves. The common peroneal nerve then

travels laterally around the head and neck of the fibula, whereas the large tibial nerve continues caudally with the popliteal vessels.

- The popliteal nerve block is often performed proximal to the point of bifurcation or at the point of bifurcation, with injection of local anesthetic in or around the common connective tissue sheath described by some as the “paraneural sheath.”^{4,5}

PATIENT HISTORY AND PHYSICAL FINDINGS

- Assess patient’s pain history and proposed surgery to determine if a popliteal nerve block is appropriate for the procedure.
- Examine patient for preexisting neuropathy and weakness.
- Assess for contraindications or increased risk of complications with regional anesthesia:
 - Patient refusal
 - Allergy to local anesthetic
 - Infection at site of nerve block or systemic infection
 - Coagulopathy
 - Preexisting neuropathy
 - Increased risk of compartment syndrome
- The patient’s surgeon and primary anesthesia team should agree with placement of block.
- Determine if a single injection nerve block or perineural catheter is indicated depending on the requirements for surgical anesthesia and postoperative analgesia. If a prolonged block is preferred for outpatient surgery, ensure that the patient will be able to care for an insensate limb at home and can be contacted for follow-up.
- Prior to starting the nerve block, ensure that the patient will be able to proceed with surgery and anesthesia (consents completed, appropriately NPO, etc.).

SURGICAL MANAGEMENT

Preoperative Planning

- Patient preparation:
 - Surgical and anesthesia consents signed
 - Monitors—blood pressure cuff, ECG, pulse oximeter, capnography
 - Supplemental oxygen via nasal cannula or facemask
 - Pillows, blankets, or tables to aid positioning

- Skin marker to mark the site laterality and surface landmarks
- Sedation to optimize patient comfort—typically midazolam and fentanyl
- Rescue drugs and emergency airway equipment available
- Supplies for single injection technique:
 - Antiseptic skin disinfectant
 - Sterile gloves, mask, hat
 - Sterile drapes or towels
 - 50- to 100-mm 20- to 22-gauge short-bevel insulated stimulating needle
 - Small syringe and small gauge needle with lidocaine for skin infiltration
 - 30 mL local anesthetic of choice
 - Nerve stimulator and/or ultrasound machine with high-frequency linear probe, sterile ultrasound probe cover, and ultrasound gel
- Supplies for continuous catheter technique:
 - Antiseptic skin disinfectant
 - Sterile gloves, gown, mask, hat
 - Ultrasound machine with high-frequency linear probe or nerve stimulator
 - 30 mL local anesthetic of choice
 - Sterile regional anesthesia tray:
 - Drapes or towels
 - Gauze
 - A 100-mm block needle, often a 17- or 18-gauge Tuohy needle
 - A flexible nerve block catheter with connector (may use stimulating catheter with nerve stimulator technique)
 - 10- to 20-mL syringe
 - Local anesthetic or saline for injection through needle
 - Extension tubing
 - Small syringe and small gauge needle with lidocaine for skin infiltration
 - Surgical skin glue
 - Transparent dressing
 - Catheter stabilization device
 - Ultrasound probe cover with ultrasound gel

Approach

- Ultrasound-Guidance Versus Nerve Stimulation
 - Nerve localization can be achieved using peripheral nerve stimulators and/or

ultrasound guidance.

- Over the past decade, ultrasound-guided nerve blocks have rapidly gained popularity because they provide several advantages compared to the nerve stimulator technique. The use of ultrasound provides direct, real-time visualization of target nerves, needle advancement, and spread of local anesthetic in the desired location.⁶ With continuous catheter techniques, the precise location of the catheter tip can be visualized. Blood vessels and smaller peripheral nerves can be identified and avoided. Research suggests that ultrasound guidance provides an improvement in time required to perform the block, block onset, and block success.^{7–10}
- For the popliteal sciatic block, ultrasound allows visualization of the precise point where the sciatic nerve bifurcates, which is variable between patients. Identifying this location is helpful in blocking both components of the sciatic nerve.
- For these reasons, although this chapter briefly covers nerve stimulator approaches, the focus will be on ultrasound-guided techniques, which have become routinely used in regional anesthesia.
- Ultrasound in-plane versus out-of-plane needle insertion approaches
 - With the in-plane approach, the needle is inserted at the side of the transducer, in line with the ultrasound beam (**FIG 2**). Because the needle is within the plane of imaging, the entire needle shaft and tip should be seen as echogenic line. In-plane approach is often used due to superior visualization of the entire needle as it is advanced toward the target.
 - With the out-of-plane approach, the needle is introduced perpendicular to the transducer (**FIG 3**). The needle crosses the plane of the ultrasound beam such that the needle shaft and tip are seen as an echogenic dot on ultrasound. Needle tip localization is more difficult with this approach. Techniques to help locate the needle tip include looking for tissue displacement, scanning for the needle tip, and injection of fluid to separate tissue planes (hydrodissection). One advantage of using the out-of-plane approach is that the needle traverses only skin and adipose tissue, avoiding muscle.
- Approaches related to patient positioning
 - A wide range of positions can be used during popliteal sciatic nerve blockade. Each is discussed and illustrated in further detail in the following section.
 - Choice of positioning is typically dictated by a combination of patient comfort, patient mobility, operator ergonomics, and the operator's personal

preference. Body habitus, pain, or the presence of external fixation devices may limit the ability of the patient to assume a lateral or prone position.

- Patients may be positioned supine or prone for nerve stimulator techniques.
- Patients may be positioned supine, lateral, or prone for ultrasound-guided nerve blocks. Regardless of the position, the ultrasound image is identical. If the out-of-plane needle insertion approach is desired, prone or lateral positioning provides better access.

FIG 2 • In-plane approach to popliteal sciatic nerve block.

FIG 3 • Out-of-plane approach to popliteal sciatic nerve block.

TECHNIQUES

■ Nerve Stimulator, Lateral Approach

- The patient is positioned supine with leg slightly elevated to visualize foot movement. This is best achieved by placing the leg on a small stack of blankets such that the foot and heel protrude beyond the blankets.
- Main landmarks are the popliteal fossa crease and the muscular groove between the biceps femoris and vastus lateralis muscles. The site of needle insertion is within the muscular groove, about 7 to 8 cm cephalad to the popliteal crease; the muscular groove may be accentuated by having the patient lift their leg off of the plane of the table. Use a skin marker to denote landmarks.
- Prepare the skin with an antiseptic solution and infiltrate the proposed needle insertion point with local anesthetic via a small gauge needle. Connect the peripheral nerve stimulator to a 100-mm 20- to 22-gauge short-bevel insulated stimulating needle. Using sterile technique, insert the needle perpendicular to the skin and advance in a horizontal plane between the vastus lateralis and biceps femoris muscles until femur is contacted; bony contact provides a reference point for nerve localization. The sciatic nerve is typically 1 to 2 cm beyond the skin-to-femur distance and located posterior to the femur (**TECH FIG 1**).
- With the nerve stimulator set to 1.5 mA, withdraw needle almost to the skin and redirect at a 30-degree angle posteriorly until foot twitch is seen, typically at a depth of 5 to 7 cm. Stimulation of the common peroneal nerve causes dorsiflexion and foot eversion. Stimulation of the tibial nerve, which is more medial, results in plantar flexion and foot inversion. Tibial stimulation is preferred because it may result in a higher rate of complete sciatic nerve block.¹¹ Local twitches of the biceps femoris muscle or vastus lateralis muscle indicates that the needle is located too superficial or anterior, respectively.
- If a motor response is not elicited, withdraw needle to skin and redirect 5 to 10 degrees more posterior.
- Once sciatic nerve stimulation is obtained, make small needle adjustments until twitches are obtained at 0.3 to 0.5 mA.
- Check for intravascular placement with gentle aspiration and then slowly inject 30 to 40 mL of local anesthetic.

TECH FIG 1 • Cross-sectional anatomy of the distal thigh (right leg 8 cm above knee).

■ Nerve Stimulator, Posterior Approach

- Position the patient prone with the leg to be blocked protruding from the end of the bed or slightly elevated on a blanket to allow for visualization of foot movement.
- Primary landmarks are the popliteal fossa crease, tendon of the biceps femoris laterally, and tendons of the semitendinosus and semimembranosus muscles medially. Knee flexion against resistance can help accentuate the tendons and identify the knee crease. The needle insertion point is about 7 cm above the popliteal fossa crease 1 cm lateral and 1 cm caudal to the apex of the popliteal fossa. Use a skin marker to denote landmarks (**TECH FIG 2**).
- Prepare the skin with an antiseptic solution and infiltrate the proposed needle insertion point with local anesthetic via a small-gauge needle. Connect the

peripheral nerve stimulator set at 1.5 mA to a 50-mm 20- to 22-gauge short-bevel insulated stimulating needle.

- Using sterile technique, insert the needle 45 to 60 degrees to the skin, then advance the needle until foot twitches are obtained. Typical depth is 3 to 5 cm from the skin. Stimulation of the common peroneal nerve causes dorsiflexion and foot eversion. Stimulation of the tibial nerve, which is more medial, results in plantar flexion and foot inversion. Tibial stimulation is preferred because it may result in a higher rate of complete sciatic nerve block.¹¹
- If a motor response is not elicited, withdraw the needle to the skin and redirect 5 to 15 degrees laterally. If there is continued difficulty localizing the sciatic nerve, withdraw needle to skin and reinsert 1 cm laterally in incremental steps.
- Once sciatic nerve stimulation is obtained, make small adjustments to the needle position to obtain foot twitches at 0.3 to 0.5 mA.
- Check for intravascular placement with gentle aspiration, and then slowly inject 30 to 40 mL of local anesthetic.

TECH FIG 2 • Positioning and landmarks for stimulator-guided popliteal block.

■ Nerve Stimulator, Continuous Catheter Technique

- Use the same procedure as for single injection nerve stimulator technique described above, but with a larger insulated stimulating Tuohy needle to allow for passage of a catheter. An in situ catheter allows for continued

dosing of local anesthetic to provide prolonged anesthesia and analgesia. Either a stimulating or nonstimulating catheter can be used:

■ Nonstimulating catheter:

- After localizing the sciatic nerve with motor response at 0.3 to 0.5 mA, inject local anesthetic to open up space for the catheter.
- Insert a catheter through the Tuohy needle and advance 3 cm past the tip of the needle. If catheter insertion is difficult, slight adjustment of the needle or direction may facilitate catheter advancement.
- Carefully withdraw needle while simultaneously advancing the catheter. Aspirate the catheter to check for inadvertent intravascular placement and secure using a catheter stabilization device and clear dressing.

■ Stimulating catheter:

- Localize the sciatic nerve with a motor response around 0.5 mA. Do not inject local anesthetic or saline through the needle or the motor response will be lost. D5W can be used if necessary.
- Insert a stimulating catheter with the nerve stimulator now attached to the catheter. Advance the catheter 3 to 5 cm past the needle tip while maintaining a motor response. If motor response is lost, withdraw and readvance the catheter. If catheter insertion is difficult, withdraw the catheter and adjust the needle slightly to facilitate catheter advancement.
- Once the catheter is in a satisfactory position, the needle can then be carefully withdrawn while advancing the catheter simultaneously. Feed additional catheter under the skin to minimize premature dislodgment. Aspirate the catheter to check for inadvertent intravascular placement and secure.

■ Ultrasound-Guided, In-Plane Needle Insertion Approach

- Of the various approaches described, this is the most commonly used approach due to ease of needle and target visualization.
- Positioning—Patients may be positioned supine, lateral decubitus, or prone (**TECH FIG 3**). Regardless of the position selected, ultrasound imaging and needling are similar. Thus, patient positioning is determined by a combination of patient comfort, patient mobility, and operator ergonomics and preference.

■ Supine position

- Position the patient supine with the operative leg elevated using blankets, pillows, or a table to accommodate an ultrasound probe beneath the thigh.
- The operator is positioned on the side to be blocked with the ultrasound screen on the opposite side of the patient.

■ Lateral decubitus position

- Position patient lateral with the procedural leg on top, knee extended. The dependent leg can be bent at the knee to enhance stability.
- Operators may choose to stand in front of the patient, facing the anterior thigh with the ultrasound probe directed toward themselves or stand behind the patient, facing the posterior aspect of the thigh, pointing the probe away from themselves.

■ Prone position

- Position the patient prone with the operative leg slightly abducted. A blanket folded under the lower leg may help relax the hamstring tendons to facilitate ultrasound transducer placement.
- The operator is positioned on the side to be blocked with the ultrasound screen on the opposite side of the patient.

■ Imaging

- Disinfect the skin with an antiseptic solution, drape the procedural area, and cover the ultrasound probe with a sterile ultrasound sheath and gel.
- Place the transducer in a transverse orientation in the popliteal fossa to obtain a short-axis view of the nerves.
- Perform a systematic survey of the surrounding structures. Identify the femur. The pulsatile popliteal artery and the accompanying vein are located posterior to the femur. The sciatic nerve appears as a hyperechoic oval structure with a honeycomb pattern that is posterior and lateral to the artery, medial to the biceps femoris muscle, and lateral to the semitendinosus and semimembranosus muscles.
- Optimize the ultrasound image by adjusting variables especially frequency, gain, depth, and focal zones. Tilting the ultrasound transducer to direct the beam caudally may enhance the visualization of the nerve by bringing the ultrasound plane more perpendicular to the nerve.
- Scan proximally and distally along the sciatic nerve to identify the bifurcation point of the common peroneal and tibial nerves. This division usually occurs 2 to 7 cm proximal to the popliteal crease and at a depth of 2

to 4 cm.

- Choose a location just proximal to the bifurcation, where the peroneal and tibial nerves are still enclosed in a common connective tissue sheath (**TECH FIG 4**).

■ Needling

- Determine the optimal needle path. Identify small vessels that should be avoided. The needle insertion point will be near the lateral aspect of the transducer.
 - Choose an insertion point lateral to the transducer. The needle will traverse the biceps femoris muscle.
 - Choose an insertion point close to the transducer to decrease the amount of muscle tissue along the needle path.
- Infiltrate the skin with local anesthetic at the insertion site. Use a 20- to 22-gauge 100-mm block needle. Flush the tubing and syringe to remove air since air will obscure the ultrasound image.
- Introduce the block needle in the same plane as the ultrasound beam with the bevel of the needle facing the probe. The needle shaft and tip should always be visualized during needle advancement.
- Carefully advance needle under direct visualization toward the nerve sheath, taking care to bring the needle close to the edge of the nerve, to avoid puncturing the nerve.
- Aspirate, then inject 1 to 2 mL of local anesthetic. Never inject or advance needle if patient complains of pain or if high pressure (greater than 15 psi) is met on injection or if the nerve is swelling. These signs dictate an immediate repositioning of the needle tip.
- If in the correct location, the hypoechoic fluid should surround the nerve completely.
- If fluid spread is not ideal, reposition needle to achieve adequate circumferential spread with a total of 20 to 30 cc local anesthetic.

TECH FIG 3 • Supine, lateral decubitus (**A**), and prone positioning (**B**) for in-plane ultrasound-guided popliteal block.

TECH FIG 4 • Ultrasound image of the sciatic nerve at its bifurcation. T, tibial nerve; CP, common peroneal nerve.

■ Ultrasound-Guided, Out-of-Plane Needle Insertion Approach

- Needle localization is more difficult with an out-of-plane approach in comparison to an in-plane approach. Because the needle crosses the plane of the ultrasound beam, the needle shaft and tip are seen only as an echogenic dot. The advantage is that the needle traverses only skin and adipose tissue, avoiding muscle.
- Positioning—Patients may be positioned lateral decubitus or prone for out-

of-plane needling. Regardless of the position selected, ultrasound imaging and needling are identical. Choose the best position based on patient comfort and operator preference.

■ Imaging

- Disinfect and prepare the site as described above.
- Place the transducer in the transverse orientation in the popliteal fossa to obtain a short-axis view of the sciatic nerve.
- Follow the same steps for imaging as with the in-plane ultrasound approach.

■ Needling

- Align the sciatic nerve in the center of the ultrasound screen and place a wheal of local anesthetic in the center of the probe, close to the probe.
- Insert a block needle through the skin wheal directed approximately 60 to 80 degrees cephalad. Aim to place the needle tip to the side of the nerve to avoid nerve trauma.
- As the needle crosses the plane of the ultrasound beam, it will appear in cross-section as an echogenic dot. Because both the needle shaft and tip have a similar appearance, track the tip with the probe as the needle is advanced. If not directly visualized, the needle tip may be inferred by tissue displacement along the needle path as well as hydrolocation.
- Aspirate, and then slowly inject local anesthetic while observing the fluid spread. Ideally, hypoechoic fluid should be seen spreading circumferentially around the hyperechoic nerve. Inject 20 to 30 mL of local anesthetic.

■ Ultrasound-Guided Continuous Catheter Technique

- Catheter placement provides a continuous infusion or additional boluses of local anesthetic to provide prolonged anesthesia or pain control.
- Strict aseptic technique is crucial for prevention of infectious complications.
- Both in-plane and out-of-plane ultrasound-guided approaches can be utilized.
- Catheter placement utilizes the same needle placement procedure as described above but requires a larger needle for passage of a perineural catheter. After the needle is confirmed to be the correct location, an

additional 5 to 10 mL bolus of saline or local anesthetic solution is injected to facilitate catheter advancement.

- Carefully advance the catheter about 3 to 5 cm past the needle tip. If catheter insertion is difficult, withdraw the catheter and try small adjustments of the needle. Before or after needle removal, confirm catheter tip location with injection through the catheter, watching for appropriate spread.
- Carefully withdraw the needle while simultaneously advancing the catheter in different tissues. Overfeeding additional catheter under the skin may help prevent accidental dislodgment.
- Carefully secure the catheter in place with an anchoring device and clear dressing. Use a total of 20 to 30 mL of local anesthetic.

PEARLS AND PITFALLS

Identification of nerve and structures

- Knowledge of both surface anatomy and ultrasound anatomy is essential.
- Tilt the transducer beam caudally toward the foot to direct ultrasound waves perpendicular to the nerve and enhance visualization.
- Asking the patient to plantar flex and extend their foot causes the tibial and common peroneal nerves to slide against each other, known as the “seesaw sign.”¹²
- At the popliteal crease, the vessels are immediately anterior to the tibial nerve. Reduce transducer pressure to visualize the popliteal vein. Trace the nerve proximally to where the common peroneal joins to form the sciatic nerve.

Nerve block coverage

- In combination with a saphenous nerve block, popliteal block provides complete sensory blockade below the knee.
- Popliteal block does not cover thigh tourniquet pain. The patient may require general anesthesia or a femoral nerve block instead of a selected saphenous when a thigh tourniquet is used.

Approach

- Ultrasound imaging allows for various patient positions and needle approaches. Choice of approach depends on patient and operator comfort.

Catheter placement

- For a continuous technique, once the needle is in optimal position, inject a small amount of saline or local anesthetic to facilitate

catheter advancement.

- Check the catheter tip location by injecting a small volume of saline or local anesthetic with ultrasound visualization.
- Feed additional catheter in the muscle or subcutaneous tissue to prevent inadvertent catheter dislodgment.

Postblock safety

- Always counsel patients on fall risk and injury risk to a numb extremity. Providing a boot will improve stability. Patients must not weight bear until the block has fully resolved.
- Both thorough preoperative counseling and clarification of patient expectations are essential to the successful management of the block.

POSTOPERATIVE CARE

- Block onset time varies dramatically from 10 to 45 minutes depending on patient, medication selection, and proximity of the injectate to the nerve.
- Thorough patient education is essential for the successful function and safety of the nerve block.
- All patients should be followed postoperatively for block resolution and to detect complications.
- All patients with nerve block catheters should be evaluated daily while in the hospital or contacted by phone if receiving nerve block infusion at home.
- Catheter leakage at the site of insertion and catheter dislodgment may occur. Patients should have additional analgesics available for breakthrough pain or in the event of catheter dislodgment.

COMPLICATIONS

- Injuries as a result of an insensate limb—Instruct patient, nurses, and caregivers on proper care of an insensate extremity including fall precautions and positioning. Avoid nerve blocks in patients who have a high risk of compartment syndrome.
- Infection—Use strict aseptic technique, avoid perineural catheter placement in patients with active infections, and limit duration of perineural catheter use.
- Hematoma formation—Ultrasound imaging and avoidance of vascular trauma or multiple needle passes may minimize risk.
- Nerve injury—Rare complication from direct needle trauma or intraneural injection; usually resolves in weeks to months. Risk may be increased in patients with preexisting nerve injury. More common causes of nerve injury

include surgical, ischemic, and compressive nerve injuries. Avoid tourniquet placement over nerve block site to decrease ischemic nerve injury. Avoid needle advancement or injection if the patient complains of pain or paresthesias or if increased pressure (greater than 15 psi) is felt during injection. Avoid needle advancement during an ultrasound-guided procedure if the target or needle tip is poorly visualized.

- Local anesthetic toxicity—Avoid intravascular injection by aspirating prior to injection and aspirating frequently during injection. Patients should be monitored following the nerve block. Have rescue medications, such as lipid emulsion, and emergency airway equipment readily available.

CHAPTER Ankle Block

Andrew Lyons and Fred Mihm

DEFINITION

- Ankle block is a highly effective peripheral nerve block that results in anesthesia of the entire foot. This block has been shown to reduce both postoperative pain and opioid consumption following foot surgery.^{1,2}
- Though a number of injections are required, a low total volume of local anesthetic injectate is required to successfully perform an ankle block.
- The ankle block can be useful due to its relatively low-risk profile, technical ease, and efficacy.
- Typical plastic surgery procedures that utilize this block include tendon repair and distal foot or toe amputation.

ANATOMY

- An ankle block is the selective blockade of both the saphenous nerve and the four terminal branches—deep and superficial peroneal, tibial, and sural nerves—of the sciatic nerve.
- Ankle block is considered to be an easy block to perform because the terminal nerves of interest are generally superficial and are reliably located next to readily identifiable surface landmarks.

POSITIONING AND PREPARATION

- Ankle block is most commonly performed with the patient in the supine position.
- Elevation of the foot by bolstering the calf with a pillow will facilitate access to the ankle (**FIG 1**).
- It is helpful to have an assistant available to gently place the leg in either

internal or external rotation.

MATERIALS

- Topical disinfectant (chlorhexidine, betadine, or equivalent)
- Sterile gloves
- Ultrasound with a small, high-frequency linear probe
- 20-mL sterile syringe
- 22-gauge short-bevel block needle
- Non-epinephrine containing local anesthetic

GENERAL CONSIDERATIONS

- The goal of the ankle block is to deliver local anesthetic adjacent to the five nerves that innervate the foot.
- Needle insertion can be either in-plane or out-of-plane for each of the terminal nerve blocks that comprise an ankle block.
- 3 to 5 mL of local anesthetic per nerve is required for a successful block.
- The tibial nerve should be addressed before blocking the other nerves because of its relatively larger size and resultant resistance to the effects of local anesthetics.
- The use of ultrasound guidance augments the clinical efficacy of an ankle block, especially for the tibial and deep peroneal nerves, which are relatively deep.³⁻⁶
- A small high-frequency linear ultrasound transducer is recommended.

FIG 1 • Proper positioning of the foot is essential when performing an ankle block. The patient is placed supine

and a pillow is used to facilitate access to the ankle.

TECHNIQUES

■ Tibial Nerve

- Landmark technique: Inject 3 to 5 mL of local anesthetic in the deep tissue of the ankle posterior to the medial malleolus and the posterior tibial artery. The injection is typically performed after the needle contacts the underlying bone (tibia) and is withdrawn 0.5 to 1 cm.
- Unlike the other nerve blocks that comprise an ankle block, a nerve stimulator can be used as an adjunct for nerve block; plantar flexion of the toes indicates proper needle placement with tibial nerve stimulation.
- Ultrasound-guided technique: Place the ultrasound probe horizontally just superior and posterior to the medial malleolus to visualize the tibial nerve (**TECH FIG 1A**).
 - The tibial nerve is superficial to both the belly and the tendon of the flexor hallucis longus.
 - The tibial nerve lies immediately posterior to the posterior tibial vessels of the ankle; at this level, the nerve and vessels may be easily mistaken for one another. Sometimes, a fascia separates the nerve from the vessels, placing the nerve deeper and partially behind the vessels (**TECH FIG 1B**).
 - Color Doppler imaging may be helpful in distinguishing the posterior tibial artery from surrounding structures.

TECH FIG 1 • **A.** Tibial nerve block is performed by injecting local anesthetic into the deep tissue of the

ankle. **B.** Ultrasound image of a tibial nerve block demonstrating the nerve (*TN*) in the deep tissue of the ankle just posterior to the vascular complex formed by both the posterior tibial artery (*pTA*) and the posterior tibial vein (*pTV*). Note the flexor hallucis longus (*FHL*) is found deep to the nerve. The Achilles tendon (*AT*) serves as the most posterior boundary of the image.

■ Deep Peroneal Nerve

- Landmark technique: Identify the extensor hallucis longus tendon and the dorsalis pedis pulse on the dorsal aspect of the ankle. Insert the block needle between these two landmarks perpendicular to the skin and inject 3 to 5 mL of local anesthetic into the deep tissue.
- Ultrasound-guided technique: Place the ultrasound probe in a transverse orientation over the anterior foot just above the line joining the malleoli (**TECH FIG 2A**) to visualize the deep peroneal nerve adjacent to the dorsalis pedis artery (**TEHC FIG 2B**).

TECH FIG 2 • A. Deep peroneal nerve block is performed by injecting local anesthetic into the deep tissue of the anterior ankle. **B.** Ultrasound image of a deep peroneal nerve block demonstrating the deep peroneal nerve (*DPN*) located lateral to the distal-most branch of anterior tibial artery (*ATA*), also known as the dorsalis pedis artery. Branching of the anterior tibial vein (*ATV*) is common at this location.

■ Superficial Peroneal Nerve

- Landmark technique: Identify the line between the injection point for the deep peroneal nerve block and the lateral malleolus. Inject 3 to 5 mL subcutaneously along this line.
- Ultrasound-guided technique: Place the ultrasound probe in a transverse orientation just lateral to the deep peroneal nerve (**TECH FIG 3A**) to allow for visualization of the superficial peroneal nerve (**TECH FIG 3B**).

TECH FIG 3 • A. Superficial peroneal nerve block is performed by injecting local anesthetic into the subcutaneous tissue of the ankle just lateral to the location of deep peroneal nerve block. **B.** Ultrasound image of a superficial peroneal nerve block demonstrating the superficial peroneal nerve (SPN) in the subcutaneous tissue along the line between the location of the deep peroneal nerve and the lateral malleolus. This nerve is sometimes difficult to visualize using an ultrasound.

■ Sural Nerve

- Landmark technique: Inject 3 to 5 mL of local anesthetic in the subcutaneous plane along the line formed between the lateral malleolus and the Achilles tendon.
- Ultrasound-guided technique: Place the ultrasound probe just posterior to the lateral malleolus to visualize the sural nerve (**TECH FIG 4A**).
 - The sural nerve lies adjacent to the short saphenous vein in the groove between the Achilles tendon and the peroneus brevis muscle (**TECH FIG**

4B).

TECH FIG 4 • A. Sural nerve block is performed by injecting local anesthetic into the subcutaneous tissue of the groove between the lateral malleolus and the Achilles tendon. A calf tourniquet may facilitate the ultrasound imaging of this block by enlarging the short saphenous vein. **B.** Ultrasound image of a sural nerve block demonstrating the sural nerve (SN) in the groove between the Achilles tendon (AT) and the peroneus brevis (PB) muscle. The short saphenous vein (SSV) is anterior to the sural nerve.

■ Saphenous Nerve

- Landmark technique: Inject 3 to 5 mL of local anesthetic in the superficial tissue of the ankle 1 cm anterior to the medial malleolus.
- Ultrasound-guided technique: Place the ultrasound probe in a transverse orientation, just anterior to the medial malleolus (**TECH FIG 5A**) to visualize the saphenous nerve traveling lateral to the great saphenous vein (**TECH FIG 5B**).

TECH FIG 5 • A. Saphenous nerve block is performed by injecting local anesthetic into the subcutaneous tissue of the ankle just anterior to the medial malleolus. A calf tourniquet may facilitate the ultrasound imaging of this block by enlarging the great saphenous vein. **B.** Ultrasound image of a saphenous nerve block demonstrating the saphenous nerve (SN) just posterior to the great saphenous vein (GSV).

■ Complications

- Multiple injections about the ankle may result in significant patient discomfort. IV sedation can be used to enhance patient comfort during the procedure.
 - Intravascular injection is uncommon and the risk for local anesthetic toxicity is low, as small volumes of local anesthetic are generally used. The absence of epinephrine from the local anesthetic solution eliminates the risk of intravenous epinephrine toxicity and reduces risk of ischemia of the anesthetized foot.
 - Induration of the superficial tissues around injection sites is not uncommon.
 - Ankle hematoma as a result of vascular injury may also occur, but is usually self-limited.
-

CHAPTER Epidural Anesthesia

Rachel C. Steckelberg, Jean-Louis Horn, and Sarah Madison

DEFINITION

- Neuraxial anesthesia is a type of regional anesthesia technique in which anesthesia medication is injected into the tissue surrounding the nerve roots as they exit the spine (eg, epidural anesthesia) and/or directly into the cerebrospinal fluid (eg, spinal anesthesia or subarachnoid anesthesia).
- Continuous epidural anesthesia is a neuraxial anesthetic technique that may be used for postoperative analgesia, surgical anesthesia, and obstetric analgesia.
- Epidural anesthesia may be used to provide anesthesia at any level below the chin, either alone or in combination with general anesthesia.
- Epidural anesthesia may be administered as a single injection or as a continuous infusion via a catheter.
- The location of the epidural placement determines the distribution of analgesia. An epidural block may be performed at the cervical, thoracic, lumbar, or sacral (eg, caudal) levels.
- A continuous infusion of local anesthesia and/or opioid pain medication may provide postoperative pain control for several days after surgery.
- Motor block with an epidural may range from none to complete, depending on the choice of drug, concentration, dosage, and/or level of administration.
- Epidural analgesia is often part of a multimodal regimen that also includes systemic medications.

ANATOMY

- The epidural space surrounds the spinal meninges (eg, dura mater) and the spinal nerve roots as they course outward to become peripheral nerves. It also contains venous plexuses, lymphatics, and fat tissue.

- Knowledge of surface anatomy landmarks is essential for safe and reliable epidural placement (Table 1).
 - In the cervical area, the most prominent spinous process is usually C7.
 - The inferior angle of the scapula can be used to estimate the level of the T7 spinous process with the arms located at the side.
 - The spinal cord terminates at level L1 in adults. The dural sac terminates at S2.
 - The body of L4 and/or the interspace between L4 and L5 spinous processes typically can be found by drawing a line between the highest points of both the iliac crests (Tuffier line).
 - The line connecting the posterior superior iliac spine (PSIS) crosses at the level of the S2 posterior foramina.
 - The sacral hiatus is located by palpating for a depression (eg, the sacral hiatus) just above or between the gluteal clefts and above the coccyx. This is the point of entry for caudal epidural blocks.
 - By counting up or down from these surface anatomy reference points, other spinal levels can be identified.
- Epidural anesthesia may be performed at any level of the spinal cord. However, each epidural location (cervical, thoracic, and lumbar) has unique anatomic features (Table 2).
- The angle of the spinous processes become progressively less angled closest to the base of the spine. For example, the spinous processes of the cervical and lumbar spine are more horizontal than the spinous processes in the thoracic spine, which are typically slanted in a more caudad direction and can overlap significantly. Thus, the technique for placement of the epidural needle varies considerably depending on the level selected.
- The ideal location of epidural placement is at the same dermatome of the surgical incision.

Table 1 Anatomic Landmarks for Identifying Vertebral Levels for Epidural Injection

Anatomic Landmark	Features
C7	Vertebral prominence (most prominent spinous process in neck)
T3	Root of spine of scapula
T7	Inferior angle of scapula

L4	Line between iliac crests
S2	Line between posterior inferior iliac spines
Sacral hiatus	Depression or groove above or between gluteal clefts directly above the coccyx

Table 2 Anatomic Features of Cervical, Thoracic, and Lumbar Spine Regions

Anatomic Feature	Cervical	Thoracic	Lumbar
Size	Small	Larger	Largest
Spinous process	Slender, often bifid (C2-C6)	Long and thick, project inferiorly	Short and blunt, project posteriorly
Transverse process	Small	Large	Large and blunt
Size of intervertebral discs	Thick (compared to vertebral bodies)	Thin (compared to vertebral bodies)	Very large

PATIENT HISTORY AND PHYSICAL FINDINGS

- A preoperative history and physical must be performed prior to epidural placement. Particular attention should be paid to anesthetic history, preexisting neuropathies, history of bleeding diatheses, medication history (especially any use of blood thinning medications), medication allergies, a history of prior neuraxial anesthesia and/or spine surgery (including spinal fusion surgery), and any history of spine disorders (including spina bifida and/or scoliosis). If imaging of the spine is available and would be useful for epidural placement, it should be reviewed.
- Physical exam should pay particular attention to any localized infections, masses, or other irregularities at the site of the planned epidural placement or surrounding areas.
- Contraindications to epidural anesthesia include patient refusal, bleeding disorders, severe hypovolemia, elevated intracranial pressure, infection at the site of epidural needle placement, flow-limiting cardiac lesions such as mitral or aortic valve stenosis, and local spinal pathology.

IMAGING

- When available, previous imaging of the spine should be reviewed, but routine imaging is not typically required prior to epidural placement.
- Preinsertion ultrasound will assist in accurate identification of the vertebral level of interest, the midline, and the depth of the epidural space (**FIG 1**).^{1–3}

NONOPERATIVE MANAGEMENT

- The balance of risks and benefits must be considered for every interventional technique, including epidural anesthesia. Depending on a number of factors (including patient history, anatomy, surgery type, etc.), it may be more appropriate to employ alternative methods of analgesia, including peripheral nerve blocks and/or systemic medications for pain control.
- Careful attention must be paid to the maximum dose of additional opioid or other local anesthetic medications used for pain control when an epidural is in place.
- Nonopioid pain medications can also be useful adjuncts to epidural anesthesia/analgesia.

SURGICAL MANAGEMENT

- Epidural anesthesia is indicated for postoperative analgesia of any surgical procedure below the level of the neck.
- Thoracic epidurals are rarely used for primary surgical anesthesia, but more commonly for intraoperative and postoperative analgesia.
- Single injection or catheter techniques are useful for chronic pain management.
- Infusions via an epidural catheter are helpful in providing prolonged analgesia and may enhance postoperative ventilation in patients with underlying lung pathology following thoracic or chest wall surgery.
- Local anesthetic via epidural administration will block sympathetic, sensory, and motor nerves. The effects are dependent on the volume, concentration, and type of medication administered via the epidural.

FIG 1 • Ultrasound of the lumbar and thoracic spine for epidural placement.

Preoperative Planning

- Surgical site, extent of incision, anticipated degree of postoperative pain, and/or any preexisting conditions (bleeding disorders, preexisting neuropathies, etc.) that may increase the risk of complications should be discussed among the care team prior to epidural placement.
- If an epidural anesthetic is under consideration, the risks and benefits should be discussed with the patient. The patient must be informed and prepared for neuraxial anesthesia and the epidural must be an appropriate anesthetic technique for the type of surgery.
- Epidural anesthesia is rarely considered an appropriate mode of analgesia for outpatient procedures.
- Neuraxial anesthetic techniques, such as epidural anesthesia, should only be performed in facilities that have the equipment and drugs needed for intubation, resuscitation, and general anesthesia available.

Positioning

- The most common patient positions for epidural placement are sitting and lateral.
- In very obese patients, it may be easier to appreciate the anatomic midline with the patient in the upright (eg, sitting) position.
- In the sitting position, the patient should rest the elbows on his or her thighs or a table, or should hug a pillow. The bed should be flat and the patient's hips level to the bed.
- The patient should be instructed to arch his/her back to provide spinal flexion.

- Arching the back like a “mad cat” maximizes the area between the adjacent spinous processes and brings the spine closer to the skin surface (**FIG 2A**).
- Alternatively, the lateral decubitus position may be considered for epidural placement. In this position, the patient lies on his or her side with knees flexed into the chest and pulled high, assuming the “fetal” position (**FIG 2B**). An assistant should help the patient hold this position.

Approach for Lumbar and Thoracic epidurals

- Depending on the level of desired epidural placement, the epidural space may be approached either medially (more common for lumbar epidurals) or paramedially (more common for thoracic epidurals).
- Midline Approach: The patient should be positioned with the back plane perpendicular to the floor, so that as the epidural needle passes through the back tissues into deeper tissues, it will stay midline. The needle entry site should be between two spinous processes at the level of interest.
- Paramedian Approach: The paramedian approach is preferred for thoracic epidurals, or when the placement is difficult (due to severe arthritis, kyphoscoliosis, and/or prior spine surgery, etc.).

FIG 2 • A. Positioning for epidural placement (Sitting).
B. Positioning for epidural placement (Lateral).

TECHNIQUES

■ Preparation

- Position the patient as described above and apply standard monitors: blood pressure, ECG (electrocardiogram), end tidal CO₂ (carbon dioxide), and pulse oximetry.
 - Intravenous sedation (such as midazolam and/or fentanyl) may be administered for patient comfort.
 - The spinous processes are typically palpable and can be used to identify the midline and the desired site of epidural needle placement, as described above.
 - A sterile field is obtained by cleansing the area with chlorhexidine or similar solution before placing a fenestrated drape.
-

■ Epidural Placement

- After sterile skin preparation, a skin wheal is placed using a small gauge needle (such as 27 gauge) to inject local anesthetic at the desired site of epidural needle placement.
- A 17- or 18-gauge Tuohy needle is generally used for epidural catheter placement in adults.
- When using a midline approach, the needle is introduced at the midline and directed slightly cephalad (**TECH FIG 1A**).
- When using a paramedian approach, the needle is introduced approximately 2 cm lateral to the inferior aspect of the superior spinous process of the desired level. The needle is then advanced at a 10- to 30-degree angle toward the midline (**TECH FIG 1B**).
- When performing a lumbar or cervical epidural block, the needle is directed only slightly cephalad. When performing a thoracic epidural block, the needle must be directed more acutely to access the epidural space.
- The initial subcutaneous tissues offer little resistance initially to the needle passage. Note: if the paramedian approach is utilized, often the needle is lateral to most of the interspinous ligaments and penetrates the paraspinal muscles; it may encounter little resistance initially.
- As the needle passes deeper, it will pass through supraspinous and interspinous ligaments, and resistance will begin to increase.
- Using the loss-of-resistance technique during epidural placement, a syringe with a freely moveable plunger is attached to the epidural needle and filled

with either saline or air.

- If the needle is correctly positioned in the ligament, the plunger will meet with resistance. However, once the needle passes into the epidural space, there will be a sudden loss of resistance, and the air or saline will freely inject with no rebound.
- Thus, the epidural space is located by the passage of a needle from an area of high resistance (ligamentum flavum) to an area of low resistance (the epidural space).
- Once the epidural space is located, a flexible epidural catheter is fed through the needle into the epidural space to the desired depth, typically 3 to 5 cm.
- After the epidural catheter is in place and secured, aspiration is recommended to ensure no CSF or blood can be aspirated.
- A test dose (typically 3 mL of lidocaine 1.5% with 5 µg/mL epinephrine) is injected via the catheter, and the patient is observed for signs and symptoms of intravascular, subdural, or subarachnoid injection.

TECH FIG 1 • A. Midline needle insertion technique for epidural placement. **B.** Paramedian needle insertion technique for epidural placement.

■ Anesthetic Administration

- Local anesthetic (with or without opioid) is then slowly titrated by bolus or continuous infusion through the catheter to provide analgesia.
- Local anesthetic selection is based on the desired speed of onset, degree of motor blockade, and duration of anesthesia. Chloroprocaine, lidocaine, and mepivacaine are short-acting local anesthetics commonly used for surgical

anesthesia. Longer-acting agents include ropivacaine and bupivacaine.

- Local anesthetic dose may be estimated by using 1 to 1.5 mL local anesthetic per desired dermatomal level of blockade. Once the initial blockade has regressed 1 to 2 dermatomal levels, a second dose of approximately 50% of the initial dose should maintain the original level of anesthesia. A continuous infusion can also maintain anesthesia. The rate of infusion depends on the concentration and type of local anesthetic chosen, the use of adjuvant medications in the infusate, and patient-specific factors. Typically, a rate of 6 to 8 mL/h is adequate.
- Dilute formulations of local anesthetics may be used in combination with fentanyl and/or hydromorphone to provide postoperative analgesia.
- Ropivacaine may produce less motor block than a similar concentration of bupivacaine while maintaining a satisfactory sensory block.
- The dose of epidural medication may need to be decreased in parturient, obese, and elderly patients. This may be due to several factors, including a potential for reduced CSF and/or a decrease in total epidural space in these patient populations. In addition, hormonal factors in the parturient patient population have been proposed to make neural endings more sensitive to local anesthetics.
- The addition of epinephrine to epidurally administered lidocaine may prolong the duration of nerve block by up to 50%. The prolongation of blockade with epinephrine added is less dramatic when using other local anesthetics, such as bupivacaine and/or etidocaine.
- Infusions are generally continued for 2 to 5 days following the surgery, depending on patient characteristics and the nature of the surgical procedure for which it was placed.

PEARLS AND PITFALLS

Sterility

- Sterile conditions must be maintained at all times when placing an epidural.

Locating the epidural space

- Placement of the needle should be done logically, based on 3D understanding of the anatomy. Needle redirection should not be random. Systematic small angle needle changes should be made.

Intravascular or intraneural injection/local anesthetic toxicity (LAST)	■ Aspiration for detection of blood or CSF is recommended prior to injection through the needle or catheter to avoid toxic side effects if epidural medication is injected intrathecally or intravascularly. Test dosing may be helpful to avoid accidental intrathecal or intravascular bolus.
Segmental block	■ May be due to septations within the epidural space. Spread of medication within the epidural space is gravity dependent. A patchy block may be corrected by injecting additional local anesthetic with the patient positioned to optimize coverage of the areas that are spared. Sacral sparing may occur due to the large size of the L5, S1, and S2 nerve roots.
Unilateral block	■ May occur if medication is delivered via a catheter that has either exited the epidural space and/or coursed laterally.
Failed epidural blocks	■ The loss of resistance technique is somewhat subjective. Local anesthetic injection may be misplaced between ligaments or paraspinal muscles. The paramedian approach can be more challenging since the needle travels through softer tissues with false loss of resistance. Epidural space anatomy may be variable, making the spread of local anesthetics less predictable.
Block assessment	■ The extent of sensory blockade may be assessed using a blunt needle tip, cold, and/or other stimulus.

POSTOPERATIVE CARE

- Following placement of an epidural, patients should continue to be monitored for local anesthetic toxicity as long as the epidural medication is infusing. Typically, this is done by clinical exam. Early signs and symptoms of local anesthetic toxicity include tinnitus, blurred vision, dizziness, tongue paresthesias, and/or perioral numbness. Symptoms may progress to seizures and/or cardiac arrest if toxicity is severe and/or not treated early.
- Maximum recommended dose(s) for some commonly used local anesthetics: chloroprocaine and procaine 12 mg/kg; lidocaine and mepivacaine 4 to 5 mg/kg (7 mg/kg with epinephrine); bupivacaine and ropivacaine 3 mg/kg.
- The dermatomal level of sensory blockade may be assessed to determine the level of sympathectomy.
- Patients should be assessed at least once daily until the epidural is removed.

This includes an evaluation of epidural function, query on side effects, determination of patient-controlled epidural analgesia (PCEA) usage, degree of motor block, and a check of the insertion site and dressing.

- Depending on the epidural medication in use, patients should be educated on possible weakness and fall risk and should be tested for muscle strength before ambulation.
- Patients should be encouraged to supplement their epidural analgesia with nonopioid systemic analgesics as needed.
- Routine dressing changes are not necessary and may increase the risk of infection or catheter dislodgement. The dressing covering the epidural insertion site should be left alone until the epidural catheter is removed.
- Patients should be continually monitored by nursing staff for signs and symptoms of epidural hematoma and/or epidural abscess, including back pain, fever, and numbness or weakness that is progressive or in excess of what is expected. These symptoms should prompt immediate evaluation by the anesthesia team. If epidural hematoma or abscess is suspected, imaging and neurosurgical consultation for surgical decompression should occur within hours of the onset of symptoms to reduce the risk of permanent complications.

OUTCOMES

- In addition to providing excellent postoperative anesthesia, epidural anesthesia has been shown to be an important factor in the survival rate of flaps in breast reconstruction plastic surgery cases due to the effects on the distribution of direct blood flow to the microcirculation.⁴
- A continuous thoracic epidural infusion is associated with reduced bleeding due to hypotension during combined plastic surgeries involving breast, abdomen, gluteus, and liposuction.⁵
- Pain management strategies that include epidural anesthesia may be associated with reduced morbidity and cost savings in abdominal wall reconstruction surgeries.⁶
- Epidural use is also associated with shortened length of hospital stay.⁶

COMPLICATIONS

- In general, the use of epidural anesthesia is associated with a very low rate of severe or disabling neurologic complications.
- Overall, long-term complications (neurologic or otherwise) are very rare with epidural placement. The incidence of serious complications following regional

anesthesia (including epidural, as well as spinal anesthesia, peripheral nerve blocks, and intravenous regional anesthesia) is estimated to be 0.01%.⁷

- Undiagnosed spinal stenosis has been identified as a risk factor for cauda equina syndrome and paraparesis.⁸
- Postdural puncture headache (PDPH) is a potential complication of epidural placement that may occur after a “wet tap,” in which the epidural needle passes through the epidural space and into the subarachnoid space. Subarachnoid placement of the epidural needle is often made immediately apparent by the free flow of CSF. Occasionally, however, the findings are subtler, and subarachnoid placement of the epidural catheter is detected by aspiration of CSF or by induction of a dense block with the test dose. Typically, PDPH is described as bilateral, frontal, or retro-orbital, with extension into the neck. It is characterized by symptom alleviation in the supine position, and worsening when upright (“postural headache”). PDPH is postulated to be due to leakage of CSF from a defect in the dura and intracranial hypotension. Initial treatment is conservative and includes administration of IV fluids, recumbent positioning, analgesics, and caffeine. Epidural blood patch may also be considered if conservative treatment fails, although many PDPH are self-limited.
- Neuropathies from epidural placement are rare. Epidural abscess and/or hematoma must be ruled out immediately (see below). Prolonged neuropathy related to epidural placement may be associated with paresthesias from the needle or catheter during placement, multiple attempts at block placement, and/or a technically difficult block. Peripheral neuropathies may be due to direct trauma to the nerve roots. Not all neurological deficits following regional anesthetic are always due to the block.⁸
- Epidural abscess is a rare complication of epidural placement and is a medical and surgical emergency. Symptoms of an epidural abscess are often insidious and delayed and progress from unexplained back or vertebral pain, to nerve root or radicular pain, then motor or sensory deficits, and finally paraplegia and/or paralysis. Prognosis is strongly related to the stage at the time of diagnosis. If suspected, catheter should be removed, antibiotics started, and neurosurgery consulted.⁸
- Epidural hematoma is another rare complication of epidural placement. Risk factors include a pre-existing bleeding diathesis or use of anticoagulation medication(s). The American Society of Regional Anesthesia (ASRA)

guidelines should inform timing of epidural placement/removal and dosing of anticoagulation when such medications are indicated. Symptoms of hematoma include severe, sharp back and/or leg pain with motor weakness, and/or sphincter dysfunction. Surgical decompression must occur within 24 hours, and as soon as possible to maximize the chance of recovery.

- Local anesthetic systemic toxicity (LAST) is a rare but potentially deadly complication. Minimize risks with careful dose calculation.

Section II: Foot, Ankle, and Lower Leg

5 Fasciotomy of the Thigh, CHAPTER Lower Leg, and Foot

Graeme E. McFarland and Jason T. Lee

DEFINITION

- Fasciotomy is indicated to treat compartment syndrome and prevent nerve injury and myonecrosis.
- Compartment syndrome most often occurs in the setting of reperfusion of an acutely ischemic limb or in severe limb trauma.
- Compartment syndrome can also occur in the setting of occlusive deep vein thrombosis (DVT) of the iliofemoral veins resulting in phlegmasia.
- Fasciotomy is indicated for treatment of active compartment syndrome, prophylactically for patients at high risk for compartment syndrome, or for those in which a reliable exam is difficult to obtain (ie, head trauma) and heightened concern for compartment syndrome.
- Isolated compartment syndrome of the thigh is rare and often due to femur fracture. The anterior compartment of the thigh is most commonly involved.¹

ANATOMY

- There are three fascial compartments of the thigh all surrounded by the strong fascia lata.
 - Anterior:
 - Muscles: Sartorius, articularis genus, rectus femoris, vastus lateralis, vastus intermedius, and the vastus medialis

- Neurovascular: Femoral nerve
- Medial (adductor):
 - Muscles: Adductor longus/brevis/minimus, gracilis, pectineus, and external obturator
 - Neurovascular: Obturator nerve
- Posterior:
 - Muscles: Adductor magnus, biceps femoris, semitendinosus, and semimembranosus
 - Neurovascular: Sciatic nerve
- There are four fascial compartments of the lower leg.
 - Anterior:
 - Muscles: Tibialis anterior, extensor hallucis longus, extensor digitorum longus, and the peroneus tertius
 - Neurovascular: Anterior tibial artery and vein and the deep peroneal nerve
 - Lateral:
 - Muscles: Fibularis longus/brevis
 - Neurovascular: Superficial peroneal nerve
 - Superficial posterior:
 - Muscles: Gastrocnemius, soleus, plantaris
 - Neurovascular: Tibial nerve
 - Deep posterior compartment:
 - Muscles: Tibialis posterior, flexor hallucis longus, flexor digitorum longus, and popliteus
 - Neurovascular: Tibial nerve, posterior tibial artery and veins, and the peroneal artery and veins
- There are technically nine compartments of the foot.
 - Medial compartment:
 - Muscles: Abductor hallucis and flexor hallucis brevis
 - Lateral compartment:
 - Muscles: Flexor digiti minimi brevis and abductor digiti minimi
 - Superficial central compartment:
 - Muscles: Flexor digitorum brevis
 - Central central compartment
 - Muscles: Quadratus plantae
 - Deep central compartment

- Muscles: Adductor hallucis compartment
- Intrinsic compartment:
 - Muscles: Four intrinsic muscles (compartments) between the 1st and 5th metatarsals

DIAGNOSIS

- Compartment syndrome can be diagnosed by directly measuring the compartment pressures with a Stryker monitor set or with an arterial line transducer system.
- Compartment pressures greater than 30 mm Hg are indicative of compartment syndrome.
- The “6 P’s” of the compartment syndrome exam are pain, paresthesia, paresis, pallor, pulselessness, and poikilothermia.
- “Pain out of proportion to examination” and pain with passive flexion are the most consistent signs of compartment syndrome.
- A clinical suspicion for compartment syndrome warrants surgical intervention regardless of compartment pressure measurement.
- Paresthesias and paresis are late signs of compartment syndrome and are indicative of poor functional outcomes.
- Severe pain of the foot along with dorsal swelling can indicate compartment syndrome of the foot.²

TECHNIQUES

■ Thigh Fasciotomy (TECH FIG 1)

- Anterolateral incision is made along the mid portion of the thigh for the length of the thigh.
- Make a straight longitudinal incision through the fascia lata and reflect the vastus lateralis medially off the lateral intermuscular septum to release the anterior compartment.
- Make a small 2-cm incision in the lateral intermuscular septum and extend proximally and distally for the length of the incision to release the posterior compartment.
- To release the medial or adductor compartment, make a medial incision

longitudinally for the length of the thigh. Incise the fascia lata for the length of the incision.

TECH FIG 1 • Thigh Fasciotomy. This figure demonstrates the two-incision approach for fasciotomy of the thigh. The medial incision carried deep through the fascia lata releases the adductor compartment. The lateral incision carried deep through the fascia lata releases the anterior compartment. The lateral intermuscular septum is then incised to open the posterior compartment. All important neurovascular bundles should not be exposed with this approach.

■ Lower Leg Fasciotomy

- Anterior and lateral compartments are released through a lateral incision

made approximately 6 to 8 cm lateral to the anterior shaft of the tibia (**TECH FIG 2A**).

- The incision is carried from approximately 3 to 4 cm distal to the lateral tibial tuberosity to approximately 2 to 3 cm proximal to the lateral malleolus.
- Subcutaneous dissection is carried deep to expose the underlying fascia.
- The anterior compartment is released by making an incision in the fascia 2 cm lateral to the tibia. The fascia is then cut for the length of the incision.
- Identify the intermuscular septum between the anterior and lateral compartments. Make an incision through the fascia 1 cm posterior to the septum and then carry proximally and distally for the length of the incision, taking care to protect the common peroneal nerve proximally which lies behind the head of the fibula.
- To release the superficial and deep posterior compartments, a longitudinal incision is made medially 2 cm posterior to the medial border of the tibia for the same length as the lateral incision (**TECH FIG 2B**).
- Expose the underlying fascia and make the incision 2 to 3 cm posterior to the tibia successfully releasing the superficial posterior compartment.
- The deep posterior compartment is released by taking down the soleus muscle from its attachment to the posterior aspect of the tibia and the interosseous membrane. This needs to be carried for the length of the incision (**TECH FIG 2C**).³

TECH FIG 2 • Lower leg fasciotomy. This figure demonstrates the two-incision approach to a four compartment fasciotomy of the lower leg. **A.** Lateral

incision is made 6 to 8 cm lateral to the anterior shaft of the tibia and carried proximally 3 cm distal to the tibial tuberosity and distally to 2 cm proximal to the medial malleolus. **B.** The medial incision is created 2 cm posterior to the medial aspect of the tibia and carried for the same length of the lateral incision. **C.** The anterior compartment is released by cutting the fascia anterior to the intermuscular septum and carried for the length of the incision. The lateral compartment is released in similar fashion through the fascia lateral to the intermuscular septum. The superficial posterior compartment is released by incising the fascia just deep to the medial incision. The deep posterior compartment is then released by freeing the soleus from its attachments to the tibia.

■ Foot Fasciotomy

- Dual dorsal incisions are used for release of all nine compartments.
- A dorsal medial incision is made over the 2nd metatarsal and carried medial and lateral to the 2nd metatarsal releasing the 1st and 2nd interosseous compartments. Blunt dissection is carried deep to release the central compartments and medial to release the medial compartment, if possible, posterior to the 1st metatarsal (**TECH FIG 3A**).
- A second dorsal incision is made over the 4th metatarsal and carried medially and laterally to the 4th metatarsal releasing the 3rd and 4th interosseous compartments. This can be carried laterally, posterior to the 5th metatarsal to release the lateral compartment (**TECH FIG 3B**).
- Occasionally, a medial incision is required to successfully release the medial and central compartments.

TECH FIG 3 • Foot fasciotomy. **A.** Occasionally, a medial incision is required to release the medial and central compartments. This is created along the medial border of the 1st metatarsal and carried through the medial compartment into the central compartment. **B.** Typically, a two-incision approach on the dorsal surface of the foot is all that is required. The first incision is made over the 2nd metatarsal and carried deep to the medial side to open the 1st interosseous compartment and then posterior to the 1st metatarsal to open the medial compartment. The incision is then carried deep to the lateral side of the 2nd metatarsal to open the 2nd interosseous compartment and the central compartment. The second incision is made over the 4th metatarsal. In a similar fashion, this is carried medial to open the 3rd interosseous compartment and deep to further open the central compartment. Finally, the incision is carried deep laterally to the 4th metatarsal to open the 4th interosseous compartment and then deep to the 5th metatarsal to open the lateral compartment.

Delayed diagnosis	■ Delayed diagnosis can often be catastrophic and result in functional losses, if not limb loss entirely.
Fascia release	■ Often the fascia can be released through smaller subcutaneous incisions by running scissors “blindly” along the fascia, superficially. This, however, can often result in troublesome bleeding from venous injury, or injury to the deep peroneal nerve.
Compartment release	■ Inadequate compartment release can result in ongoing compartment syndrome and disabling complications. Often, extending the subcutaneous incisions to fully expose the fascia and ensure adequate compartment release is the safest practice.
Nerve or vessel injury	■ Iatrogenic nerve or vessel injury can lead to certain disabling conditions similar to those in which the fasciotomy was initially indicated to prevent. The common peroneal and superficial peroneal nerve are the most commonly injured during lateral compartment release. To prevent this, terminate the proximal incision in the fascia 5 cm distal to the fibular head to prevent injury to the common peroneal nerve, and distally direct the incision towards the lateral malleolus to avoid injuring the superficial peroneal nerve.

POSTOPERATIVE CARE

- Patients require frequent neurovascular check every 1 to 2 hours for the initial postoperative period.
- Critical care monitoring and adequate IV fluid resuscitation are essential for renal protection in the setting of myoglobin release.
- Typically, fasciotomy wounds are initially dressed with wet to dry dressings that are changed 2 to 3 times daily to allow frequent evaluation of the underlying muscle.
- After the initial 24- to 48-hour period following compartment release, a wound vacuum dressing can be used to decrease the frequency of dressing changes and promote healing.
- Occasionally, if the limb is not too edematous, the fasciotomy incisions can be closed several days after the procedure to heal by tertiary intention.
- Frequently, skin grafting is required to ultimately heal the incision.

OUTCOMES

- Functional outcomes following fasciotomy depend mainly on the underlying

injury, as well as time to procedure and adequacy of compartment release.

- Appropriate timing of fasciotomy is essential for improved outcomes. For fasciotomies delayed greater than 12 hours from the onset of compartment syndrome, limb loss is as high as 50%, with only approximately 8% maintaining normal limb function.
- Fasciotomy wound closure can be attempted during the same hospitalization if the swelling allows for tension-free closure of the skin. Occasionally, skin graft closure is required.

6 Drainage of Abscesses of Lower Leg and Foot

CHAPTER

Michael Holland and Scott L. Hansen

DEFINITION

- Infections of the foot, ankle, and lower leg range in severity from minor local cellulitis to rapidly progressive necrotizing fasciitis.
- Abscesses are a result of infection leading to inflammation and cell death, whereby a cavity is created that is filled with a mixture of bacteria, inflammatory cells, and necrotic tissue.
- Painful areas of fluctuance can be identified on physical exam and are most commonly surrounded by signs of inflammation (redness, warmth, pain, and swelling) but may also be found in isolation.
- Abscesses of the lower extremity and foot are frequently the result of trauma creating a break in the skin's natural barrier, allowing for colonizing or environmental pathogens to proliferate in the skin and deeper subcutaneous tissues.

ANATOMY

- The lower leg, ankle, and foot are comprised of 28 bones.
- Soft tissues include the overlying skin and subcutaneous tissue as well as muscles that are divided into anatomically distinct compartments in both the lower leg as well as the foot.
 - The four compartments of the lower leg include the anterior, lateral, superficial posterior, and deep posterior divided by fascia.
 - The nine compartments of the foot include the calcaneal—communicating with the deep posterior compartment of the leg, superficial, medial, lateral, adductor, and four interosseous.
- The primary neurovascular structures include the anterior tibial, peroneal, and

posterior tibial arteries and paired veins; superficial peroneal, deep peroneal (fibular), tibial, saphenous, and sural nerves; and greater and lesser saphenous veins in the superficial tissues (**FIG 1**).

FIG 1 • Cross section of lower leg demonstrating four compartments separated by intramuscular septae, neurovascular structures, and soft tissue. (From Pansky B, Gest TR. Lower limbs. In: *Lippincott's Concise Illustrated Anatomy: Back, Upper Limb, and Lower Limb*. Vol. 1. Baltimore, MD: Wolters Kluwer; 2012:198.)

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient's initial complaint is typically of pain and swelling at the site of infection. They may also notice changes in skin color and drainage of fluid. There may be a history of antecedent trauma.
- Systemic symptoms such as fevers, chills, malaise may not be present early in the disease.
- Past medical history of diabetes mellitus, vascular disease, immunodeficiency, injection drug use prior fracture, and prior surgery may predispose to infection and abscess formation.
- Physical exam may reveal erythema, swelling, tenderness, warmth, fluctuance,

visible drainage, and eschar. Many times, erythema and tenderness will be the only physical exam findings, so a high index of suspicion for underlying fluid collection is necessary.

IMAGING

- Despite its inability to well characterize fluid collections, standard multiple view radiographs are the first initial test to identify any bony injury or radiopaque foreign bodies as well as gas from anaerobic bacteria. Subtle soft tissue changes may also be demonstrated but are harder to appreciate by the untrained examiner.
- Ultrasonography may show cobble stoning of the subcutaneous tissues, which is indicative of edema. Discrete, hypoechoic fluid collections may also be identified.
- When multiple abscesses are suspected or ultrasound findings are equivocal, CT with IV contrast of the lower extremity can be extremely valuable.
- MRI is similar to CT in its ability to diagnose soft tissue infections; however, its use is limited by cost and time required to obtain the study.

DIFFERENTIAL DIAGNOSIS

- Cellulitis
- Abscess
- Septic arthritis
- Necrotizing fasciitis
- Plantar fasciitis
- Seroma
- Hematoma
- Gout
- Cyst
- Tumor

NONOPERATIVE MANAGEMENT

- Antibiotic therapy alone is often insufficient to manage abscesses, and drainage is the primary treatment strategy.

SURGICAL MANAGEMENT

Preoperative Planning

- In patients who are hemodynamically unstable, antibiotic therapy should not be withheld while awaiting cultures.
- In patients who are otherwise stable, consider deferring antibiotics until cultures have been obtained.
- If hardware is present, consider need for removal with orthopedic surgery consultation, as well as need for bony debridement.
- Ensure medical comorbidities are addressed.
- Ensure appropriate laboratory investigations are obtained including complete blood count, basic metabolic panel, C-reactive protein, sedimentation rate, and blood cultures.
- Antibiotic selection should cover gram-positive organisms with methicillin-resistant *Staphylococcus aureus* (MRSA) coverage, and due to prevalence of gram-negative organisms in foot infections, gram-negative coverage should also be provided while awaiting culture results.

Positioning

- Supine position is sufficient for exposure.

Approach

- The goal is to completely drain the abscess cavity, remove any debris or dead tissue, thoroughly irrigate, and allow wound to heal by secondary intention.

TECHNIQUES

■ Abscess Drainage

- Identify abscess cavity by palpation of fluctuance and correlate to previous imaging (**TECH FIG 1A**).
- A linear incision is designed over the most fluctuant area, attempting to avoid making the incision over weight-bearing area or known neurovascular structures or tendons.
- An incision is made through the skin with a no. 15 scalpel. If the incision was designed immediately over the cavity, abscess fluid will be released immediately.
 - Ensure the incision is opened up sufficiently in a proximal and distal

direction (**TECH FIG 1B**).

- Obtain microbiology cultures, including bacterial cultures (aerobic, anaerobic) as they are most common. If there is clinical suspicion of other rare pathogens, send those as indicated such as fungal, yeast, mycobacteria, etc.
- Using a curved hemostat or Kelly clamp, spread gently throughout the abscess cavity for complete drainage.
- Gently probe the extent of the cavity in all directions to ensure that the cavity has been completely opened through the incision and that there are no residual fluid collections or loculations.
- Visualize cavity to ensure no necrotic tissues remaining. Adequately debride all necrotic tissues (**TECH FIG 1C,D**).
- If necrotic tissue, especially muscle, is encountered beyond the extent of abscess cavity, consider diagnosis of necrotizing soft tissue infection or necrotizing fasciitis, need for wide excision of all necrotic tissue, and addition of protein synthesis inhibiting antibiotics (eg, clindamycin).
- Irrigate the cavity with at least 3 L of saline.
- Pack the cavity with surgical packing, ensuring to apply enough packing to prevent the wound from closing prematurely.

TECH FIG 1 • A. Necrotic right lateral foot wound with underlying abscess. **B.** Sharp debridement and drainage of wound and abscess. **C.** Wound after debridement and drainage of abscess with continued necrotic tissue. **D.** Granulating wound prior to split-thickness skin grafting.

PEARLS AND PITFALLS

Preoperative workup	■ Failure to get bacterial cultures
Technique	■ Incomplete drainage: ensure that entirety of abscess cavity is explored and septations are taken down ■ Ensure incision is large enough ■ Use copious (generally at least 3 L of irrigation)
Postoperative care	■ Failure to ensure glycemic control
Dressings	■ Applying an occlusive dressing can result in reaccumulation of abscess and inability to monitor wound. Do not apply negative pressure wound therapy on grossly infected wound ■ Ensure enough packing is used to prevent wound from closing prematurely
Wound hazards	■ Do not probe wound with digit, as you may injure yourself with potential foreign body

POSTOPERATIVE CARE

- Surgical management with drainage alone has been recommended for small (less than 5 cm abscesses) without associated cellulitis or systemic signs of infection.
- However, a recent randomized control trial (RCT) has demonstrated superior cure rates for patients who received post drainage antibiotics for 7 to 14 days,

even in uncomplicated cases.¹

- Patients require at least twice daily dressing changes until wound heals by secondary intention.
- Negative pressure wound therapy e.g. Wound VAC may be considered for abscesses that result in large open wounds, however, should not be placed at time of initial debridement and should be placed only after wound appears healthy and without signs of residual infection.
- Blood sugar control
- Smoking cessation
- Early range of motion should be encouraged to prevent stiffness and contracture.

COMPLICATIONS

- Persistent infection
- Missed diagnosis of necrotizing infection
- Injury to neurovascular structures
- Hematoma

Excision of Soft Tissue Tumors of the Foot and Ankle

7

CHAPTER

Raffi S. Avedian, Robert J. Steffner, and Subhro K. Sen

DEFINITION

- Soft tissue tumors of the ankle may be benign or malignant (soft tissue sarcoma) and exhibit a variable natural history ranging from latency to rapid growth.
- Tumors located entirely above the muscle, fascia, or tendon are considered superficial, whereas tumors involving the fascia or located deep to it are considered deep.

ANATOMY

- The ankle is a synovial joint involving the tibia, talus, and fibula. Tendons of the leg muscles travel around the ankle in discrete groups each contained in a retinaculum (**FIG 1**).
- The anterior tibial artery and deep peroneal nerve travel anterior to the ankle joint just lateral to the anterior tibialis tendon.
- The posterior tibial artery and tibial nerve travel along the medial aspect of the lower leg, in the fascial plane between the deep and superficial compartments. At the ankle, they course posterior to the posterior tibial tendon along the medial malleolus.
- The tendons of the peroneus muscles travel along the posterior aspect of the lateral malleolus to their attachments in the foot.

PATHOGENESIS

- The mechanism for soft tissue tumor formation is not known.
- Risk factors for sarcoma development include radiation exposure,

radiotherapy, pesticide exposure, and hereditary conditions including Li-Fraumeni syndrome and retinoblastoma gene mutation.

NATURAL HISTORY

- All soft tissue sarcomas have the potential for local recurrence and metastasis.
- Soft tissue sarcomas exhibit a spectrum of natural history from slow-growing low-grade tumors with low risk of metastasis to high-grade sarcoma that may grow rapidly and pose a high risk of metastasis.
- Lungs are the most common site of metastasis. Lymph node involvement is rare.
- Angiosarcoma, clear cell sarcoma, epithelioid sarcoma, rhabdomyosarcoma, myxofibrosarcoma, and synovial sarcoma are associated with increased risk of lymph node spread compared to other sarcomas.
- Benign tumors by definition do not have metastatic potential but can grow to large sizes and cause symptoms.

A

FIG 1 • A. Cross-sectional anatomy of the ankle. Notice that the tendons are contained within a retinacular layer.
B. Oblique view of the ankle anatomy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Conducting a thorough history and examination is important to assess duration of symptoms, comorbidities, physical dysfunction, organ involvement, overall health, and patient expectations in order to best tailor treatment strategy for the individual patient.
- Many sarcomas may be asymptomatic with the only patient complaint being the presence of a mass.
- Neurovascular examination is mandatory for any extremity tumor.

IMAGING

- Magnetic resonance imaging is the principal imaging modality used to

characterize tumors, formulate differential diagnosis, define local tissue infiltration, and devise a surgical plan.

- Plain radiographs are used if there is concern for bone involvement or to demonstrate mineralization within a tumor such as vascular malformations.
- Staging for soft tissue sarcomas consists primarily of lung imaging.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis for a soft tissue tumor includes benign tumors, sarcomas, lymphoma, infection, and inflammatory lesions (eg, rheumatoid nodules).
- There are over 50 sarcoma subtypes. Common histologies include pleomorphic undifferentiated sarcoma, synovial sarcoma, leiomyosarcoma, malignant peripheral nerve sheath tumor, and liposarcoma.

SURGICAL MANAGEMENT

- The appropriate treatment for any musculoskeletal tumor is based on its diagnosis and natural history.
- Biopsy incisions are considered contaminated and must be resected at the time of definitive surgery. Care should be taken to place the biopsy in a location that does not interfere with the final surgical plan.
- Simple marginal excision is appropriate for most benign tumors, whereas wide resection with a clean margin is performed for soft tissue sarcomas.
- Given the relatively low volume of tissue in the lower leg and ankle, soft tissue reconstruction with local or free flaps is often needed.

Preoperative Planning

- A patient is considered ready for surgery after completion of staging and multidisciplinary review of pertinent imaging, pathology, and treatment strategy.
- The retinacula and tendon sheaths around the ankle are robust tissues that act as barriers to tumor penetration. Careful assessment of preoperative imaging is needed; however, these tissues often can be used as a margin around the tumor (see **FIG 1**).
- When tumor abuts, but does not encase blood vessels or nerves, they can be dissected free by leaving adventitia and epineurium on the tumor as the margin.
- The surgical plan is created by thorough study of the preoperative MRI scan. Fluid-sensitive sequences and fat-suppressed contrast images show the extent

of disease that must be accounted for in the excision. T1 fat-sensitive images show the normal anatomy best including fat planes between tumor and critical structures such as nerves and vessels (**FIG 2**).

Positioning

- Patient positioning is based on the surgeon's assessment of the critical anatomy of the surgery and how best to visualize it during surgery. Supine and lateral positions are most common.
- If a flap is to be used, the harvest must be performed using a separate back table and instruments and the surgical sites completely isolated to avoid contamination.

Approach

- The surgical approach varies based on location of the tumor.
- Previous biopsy and surgical scars are considered contaminated and must be excised en bloc with the tumor.

FIG 2 • **A.** Axial T1 MRI of a 57-year-old man with a myxofibrosarcoma on the lateral aspect of the ankle. Note that the tumor sits on the joint capsule and anterior talofibular ligament. **B.** Coronal MRI highlighting the tumor and its relationship to the surrounding anatomy. Notice that the joint capsule and

retinaculum around the peroneal tendons act as a barrier to tumor penetration.

TECHNIQUES

■ Excision of Soft Tissue Tumor of the Ankle

- Tourniquet is used at discretion of surgeon using gravity exsanguination rather than Esmarch to avoid tumor compression.
- A margin of normal skin is marked around previous biopsy incisions and incorporated into the surgical approach (**TECH FIG 1A**).
- The dissection is beveled away from the sarcoma through the subcutaneous tissue to the deep fascia or retinacular layer at a point that is clear away (ideally 1–2 cm if possible) from palpable tumor or tumor visualized on preoperative MRI.
- The deep fascia and retinacula are cut and used as the deep margin. Occasionally, the joint capsule may have to be included in the deep margin.
- Cutaneous nerves often are involved in the tumor. They should be cut away from the tumor and buried in the deep layers to minimize risk of symptomatic neuroma formation.
- If the tumor partially encases the tendons, the retinaculum or tendon sheath may be incised on the uninvolved side of the tendon and lifted off as the margin on the tumor preserving the tendon (**TECH FIG 1B**).
- An assessment of joint stability is performed, and ligament reconstruction or augmentation is performed if indicated.
- Free tissue transfer is performed to reconstruct soft tissue defects.

TECH FIG 1 • A. Photograph showing planned incision that includes wide excision of previous biopsy incision. Because the tumor is superficial, which is often the case for ankle tumors, a large paddle of skin is removed as the margin on top of the tumor. **B.** Photograph illustrating the deep dissection. The tumor was abutting the joint and partially encasing the peroneal tendons. The retinacular tissues around the tendons were opened and peeled off the tendons allowing the tumor to be removed safely while preserving the tendons. Similarly, the joint capsule, retinaculum of the extensor digitorum longus, and periosteum of the fibula serve as deep margin for the more anterior portion of the tumor.

PEARLS AND PITFALLS

Wound breakdown

- Soft tissue reconstruction should be without tension.
- Patients should be counseled about the importance of leg elevation and activity modification.

Positive margins (sarcoma excision)

- Appropriate preoperative planning is important to minimize risk of unplanned positive margins.
- Inability to primarily close a wound should not interfere with the decision to remove a tumor with a clean margin. Plan on soft

tissue reconstruction.

- Planned positive margins around critical structures such as nerves and vessels may be appropriate in certain settings.

POSTOPERATIVE CARE

- The ankle is splinted ideally in the neutral extended position.
- Weight bearing may begin once soft tissues including flaps and ligament reconstructions, if performed, have healed sufficiently, typically 6 weeks after surgery.
- Extremity elevation is recommended while patient is in bed.
- Antibiotics may be administered while drains are in place.

OUTCOMES (FIG 3)

- Oncological outcomes include local recurrence and metastasis. Surveillance for recurrence should be managed by a multidisciplinary sarcoma team. Local recurrence is higher when margins are positive.
- Functional outcomes depend on the extent of tissue resection and patient overall health status. Most patients will experience some form of disability that is proportional to the volume of soft tissue resection. Estrella et al. reported on a small series of six patients who underwent resection of foot and ankle sarcoma followed by free flap coverage. The average Revised Musculoskeletal Tumor Society (Enneking) functional score was 92.8% at average 49-month follow-up.¹

FIG 3 • **A.** Photograph immediately after completion of free anterolateral thigh flap. **B.** 5 years after surgery.

COMPLICATIONS

- Local recurrence occurs in a minority of patients with sarcoma and is more common in patients with positive margins.
- Deep infection can occur at any time after surgery and requires aggressive therapy including surgical debridement and antibiotic therapy to achieve limb salvage.
- Wound breakdown

8 Ankle and Foot Bone Tumors

CHAPTER

Robert J. Steffner, Raffi S. Avedian, and Sahitya K. Denduluri

DEFINITION

- Bone tumors of the foot and ankle are usually primary tumors. Metastatic bone cancer to sites below the knee is rare but not impossible.
- Primary bone tumors can be benign, low-grade malignant, or high-grade malignant.
- Surgery is considered for benign tumors with progressive growth or those producing symptoms. Malignant bone tumors are generally operative in both a curative and palliative setting.

ANATOMY

- There is minimal soft tissue coverage in the ankle and foot. Surgical resections requiring skin excision and/or placement of bulk cortical allograft should consider the need for soft tissue coverage to minimize the risk of infection and nonunion.
- When functional deficit and donor site morbidity for free tissue transfer are anticipated, consideration should be given to below-knee amputation. Patients may recover faster and have better long-term function with a prosthesis.¹

PATIENT HISTORY AND PHYSICAL FINDINGS

- It is important to ask patients about prior trauma and infections at the site of concern.
- A clinical history focusing on the duration of symptoms, presence of night pain, and systemic symptoms can help delineate benign from malignant etiologies.
- Physical exam focuses on the presence of prior incisions, skin mobility over

the tumor, and neurovascular status distal to the site of tumor involvement.

IMAGING

- Obtain plain radiographs of the involved site.
- Perform an MRI scan with and without contrast to assess the extent of tumor and involvement of critical structures such as tendons, nerves, and vessels. Also perform a whole bone MRI to demonstrate the extent of intramedullary involvement of tumor and look for skip lesions.
- Make every effort to obtain any prior imaging for comparison.
- Quality of imaging and the interpretation of imaging are vital for surgical planning.
- Upon diagnosis of a primary bone malignancy, staging studies are performed to assess for regional or distant metastatic disease. This generally requires a chest CT and whole body bone scan.

DIFFERENTIAL DIAGNOSIS

- Benign and malignant bone tumors can be found in the foot and ankle. Distinguishing between benign and malignant guides the extent of surgical management.
- Benign tumors include simple cyst, intraosseous ganglion, and enchondroma.
- Benign but active tumors include aneurysmal bone cyst (primary or secondary), giant cell tumor, osteoid osteoma, and, in pediatric patients, chondroblastoma.
- Malignant bone tumors include osteosarcoma, chondrosarcoma, Ewing sarcoma, primary lymphoma of bone, and metastatic carcinoma.

NONOPERATIVE MANAGEMENT

- Benign-appearing lesions that are not causing symptoms can be followed with serial imaging. Stable appearance on serial imaging studies supports nonsurgical management.

SURGICAL MANAGEMENT

- Symptomatic benign bone tumors and benign but active bone tumors are most often treated with intralesional curettage or marginal excision.
- Malignant bone tumors may require multidisciplinary management with the possible need for chemotherapy and/or radiation in addition to surgery.
- In nonmetastatic or oligometastatic primary bone cancer, the goal of surgery is

resection with negative margins.

Preoperative Planning

- If needed, size-matched fresh-frozen allografts should be coordinated from an appropriate vendor well ahead of time. The surgeon should assure that the graft has been delivered to the hospital. It is wise to have a back-up allograft available.
- Bone cuts are planned off T1-sequences from the first MRI scan. It is important to appreciate any soft tissue extensions and to look for fat planes around neurovascular structures to make sure they are free from tumor. Determination of appropriate margins is based on the specific diagnosis and the type of tissue at the level of resection.

Positioning

- Positioning depends on tumor location. Please see the “Techniques” section below.

Approach

- An oncologic approach allows for a limited tissue biopsy while maintaining the possibility of wide resection in the setting of a malignant diagnosis. If oncologic principles are followed, the majority of patients will be eligible for limb salvage.²

TECHNIQUES

■ Benign Bone Tumor of the Talus (TECH FIG 1A,B)

- Patient positioned supine with an ipsilateral hip bump on a radiolucent table
- Tourniquet used after gravity exsanguination
- Localize tumor with intraoperative fluoroscopy
- To access talar body, an oblique osteotomy of the medial malleolus or distal fibula is often required. The surgeon may predrill bone in a lag-by-technique fashion before the osteotomy. This facilitates repair at the end of the surgery.
- A cortical window or cartilage flap is created with a curette or high-speed bur to access the bone tumor (TECH FIG 1C).

- Tissue is removed and sent for frozen section. If the pathology report is consistent with a benign tumor and matches the patient's clinical history and imaging, the surgery proceeds.
- The cortical window is expanded to adequately visualize and remove the tumor through intralesional curettage.
- Tumor margins are extended with use of a high-speed bur to smooth out the internal cavity of the cyst. Adjuvant treatments such as cryosurgery (liquid nitrogen) and argon beam coagulation can penetrate bone and further the zone of tumor kill. These measures lower the risk of local tumor recurrence.³
- Care should be taken near cartilage and growth plates to avoid damage to these structures. It is appropriate to accept a higher risk of local tumor recurrence in order to avoid injury to these structures.
- The resultant bone defect is filled with a substance of the surgeon's choice. In general, we use allograft in young patients; artificial bone void filler in young adults (mixture of calcium phosphate and calcium sulfate) and cement in older individuals.
- Supplementary internal fixation may be needed in weight-bearing locations and large defects (**TECH FIG 1D**).

TECH FIG 1 • **A.** Lateral radiograph of a secondary Aneurysmal Bone Cyst of the talar body (*arrow*). **B.** Axial Fat-suppressed T2 MRI image demonstrating fluid-fluid levels. **C.** Photo after oblique osteotomy of the distal fibula to access the talar body. A cartilage flap is made to access the bone tumor. **D.** Fluoroscopic image demonstrating cancellous allograft filler in the talar body and internal fixation of the distal

fibular osteotomy (*arrow*).

■ Malignant Bone Tumors of the Foot and Ankle

General Principles

- Use separate instruments for tumor resection and bone defect reconstruction.
- Obtain a thorough preoperative neurovascular exam.
- Consider an epidural catheter that can be test-dosed before surgery and used once a postoperative nerve exam is obtained.
- Use a thigh tourniquet and gravity to exsanguinate the leg.
- Hold paralytic medications if a nerve dissection is needed.
- Ellipse biopsy tract and keep in continuity with the resected tumor.
- Generally work from normal anatomy to abnormal anatomy.
- Clip or tie any arteries or veins that could be used for microvascular anastomosis.
- Measure bone cuts several times before cutting.
- After the bone cut, send a marrow margin for frozen section from the nonresection side.
- Orient resected specimens before sending to pathology.
- Fresh-frozen allografts are opened when frozen sections are negative. The allograft should be cultured and then placed in warm water bath with antibiotics for thirty minutes before use.

Distal Fibula Resection

- Lateral position on a beanbag. Straight lateral incision (**TECH FIG 2A**).
- Anteriorly, assess relationship of tumor with extensor digitorum longus and peroneus tertius.
- Posteriorly, assess relationship of tumor with peroneus longus and brevis and flexor hallucis longus (FHL).
- At the ankle joint, release the tibiofibular ligaments, talofibular ligaments, and calcaneofibular ligament.
- Make proximal bone cut early and roll fibula to expose the intraosseous membrane (**TECH FIG 2B,C**).
- Deep to FHL is the peroneal artery and vein; the latter may need to be ligated.

- Remove the tumor and send a marrow margin for frozen section.
- No bony reconstruction is necessary.
- Use a medium suture anchor to create a soft tissue sleeve for the peroneal tendons. This maintains length-tension relationships and avoids tendon subluxation (**TECH FIG 2D**).
- If possible, use absorbable suture to approximate the extensor digitorum longus muscle belly to the peroneus brevis.
- Immobilize for 6 weeks in a short leg splint with a mold in dorsiflexion and eversion.
- Obtain recovery room radiograph to check for any tibiotalar tilt. If present, the splint will need to be changed.
- Partial progressive weight-bearing begins at 6 weeks. Long-term, the patient may need a custom ankle brace.

TECH FIG 2 • **A.** Illustration of the straight lateral approach for a distal fibula bone tumor. **B.** Anterior and posterior dissection with ellipse of biopsy tract. Notice the margin of normal tissue left with the malignant bone tumor. **C.** External rotation of the distal fibula after proximal bone cut (*arrow*). This exposes

the intraosseous membrane and posterior ligamentous structures. **D.** Use of remaining soft tissues to create a sling for gliding of the peroneal tendons. This also prevents tendon subluxation.

First Metatarsal (**TECH FIG 3A,B**).

- Supine position with a small contralateral hip bump.
- Dorsal incision that is just medial to the extensor hallucis longus (EHL) tendon. The tarsometatarsal (TMT) joint serves as the proximal extent of the incision (**TECH FIG 3C**).
- Ellipse circumferentially around the base of the great toe. If away from tumor, the skin around the great toe can be used for soft tissue coverage.
- Proximally, release the EHL tendon.
- Medially, dissect over the fascia of the abductor hallucis, leaving the muscle with tumor.
- Laterally, transect the extensor hallucis brevis.
- Come through the TMT joint proximally. The lateral aspect of the joint is close to the deep peroneal nerve and the deep plantar branch of the dorsalis pedis artery. Disarticulate and lift. Release the anterior tibialis tendon from the base of the first metatarsal and tag with suture.
- From plantar direction release the adductor hallucis and flexor hallucis brevis off the sesamoids. Transect the FHL tendon.
- Try to preserve the medial plantar artery and nerve.
- Release the intermetatarsal ligament and remove the resected specimen (**TECH FIG 3D**).
- Frozen section should be sent if there are any areas concerning for a positive margin.
- Scuff the medial cuneiform and attach the anterior tibialis tendon to this area with a suture anchor (**TECH FIG 3E**).
- Place a short leg splint for 2 weeks then allow heel weight bearing for the next 4 weeks.
- Once swelling is reduced, the patient is fit for a custom insert to go inside the shoe.
- Monitor postoperatively for lesser toe ulcers, flat foot deformity, and imbalance.

TECH FIG 3 • **A.** AP foot radiograph demonstrating an aggressive bone tumor of the first metatarsal. **B.** T1 coronal MRI showing Ewing sarcoma of the first metatarsal. **C.** Illustration of the dorsal incision with

circular ellipse around the great toe used for first metatarsal resection. **D.** Resected specimen after oncologic amputation of the first metatarsal. **E.** AP foot radiograph after surgery demonstrating suture anchor repair of the anterior tibialis tendon into the medial cuneiform.

Calcaneus

- Patient is positioned lateral on a beanbag. Blankets are used to create a platform for the top leg. Make sure the down leg will not obscure intraoperative fluoroscopic images.
- If there is concern for a postoperative equinus contracture, a gastrocnemius recession can be done before tumor resection.
- A lateral approach is made (**TECH FIG 4A**). Identify the peroneal tendons and sural nerve (**TECH FIG 4B**). Tumor extent will dictate the ability to salvage these structures. *As able, try to preserve the tenosynovium over the peroneal tendons.*
- A geometric tumor resection can utilize CT-guidance. To use this technology, a preoperative CT scan with *fiducials* or an intraoperative scan with an O-arm machine is needed. In the operating room, an array is placed close to the surgical site and points are cross-referenced between the CT scan and the patient's intraoperative position (**TECH FIG 4C**). This allows simultaneous localization in the axial, coronal, and sagittal planes.
- The angle of Gissane and posterior facet provide orientation.
- Using measurements from the preoperative MRI scans, use a sterile marker to draw the geometric cuts. If available, use CT guidance to confirm that the proposed geometric cuts are free from tumor.
- Use a microsaw to cut bone up to the opposite cortex. Use an osteotome to complete the resection. This will minimize risk to the medial plantar artery. Roll the resected bone and release the remaining soft tissue attachments (**TECH FIG 4D**).
- Perform frozen sections from the cut margins of the remaining bone as needed. Once frozen sections are negative, establish a new clean field and open reconstruction equipment.
- Use wax paper from surgical gloves to draw the bone defect.

- A fresh frozen femoral head allograft is opened and prepared as noted in “General Principles.”
- Fashion the allograft with a microsaw to fit the wax paper template. Maintain the subchondral bone of the femoral head for the plantar surface of the allograft (**TECH FIG 4E**).
- Place cancellous allograft at the femoral head allograft-host bone junction.
- Temporarily stabilize with k-wires.
- Using fluoroscopic views of the lateral foot and Harris axial, navigate percutaneous screws from the heel into the anterior process of the Calcaneus. Try to minimize the number of drill holes through the allograft (**TECH FIG 4F**).
- Soft tissue closure may be primary or require flap reconstruction.
- In general, a short leg splint is applied for 6 weeks. Front foot weight bearing is then allowed until 3 months postoperatively. Partial progressive weight bearing is then initiated.

TECH FIG 4 • A. Illustration of the lateral approach to the calcaneus used for tumor resection. **B.** Ellipse of

the biopsy tract with identification of the peroneal tendons, which were amenable to preservation. **C.** Placement of the array into the fifth metatarsal. The array is used to couple the patient's intraoperative anatomy to a CT scan to facilitate localization during the geometric resection of tumor. **D.** The tumor is gently rolled out, and soft tissue attachments from the medial side are released to remove the tumor. **E.** Placement of the fashioned fresh-frozen allograft femoral head into the calcaneal defect. The subchondral surface is used on the plantar aspect of the foot. **F.** Follow-up lateral radiograph of the femoral head allograft stabilized with two percutaneous 2.7-mm screws. The host-allograft junctions appear healed. This patient required free tissue transfer for soft tissue coverage.

Distal Tibia

- Supine position without a hip bump.
- Incision is along the anteromedial tibia (**TECH FIG 5A**).
- Save the saphenous vein and nerve if possible.
- Release the posterior compartment fascia, identify and protect the tibial nerve and posterior tibial artery, which is found between the flexor digitorum longus and FHL muscles.
- Release the anterior compartment fascia, identify and protect the deep peroneal nerve and anterior tibial artery, which is found between the tibialis anterior and EHL muscles.
- The neurovascular bundle at the anterior ankle goes from medial to lateral relative to the EHL tendon.
- Measure resection lengths off the medial malleolus.
- Mark rotation on the nontumor side both proximal and distal to the bone cuts.
- Use retractors to protect the soft tissues around the tibia. Use the microsaw to cut bone while irrigating to prevent bone necrosis from heat.

- Roll the resected segment and release the intraosseous membrane.
- Check marrow margins from the intramedullary canal of the remaining bone at the proximal and distal ends (**TECH FIG 5B**).
- Measure the length of the resected specimen (**TECH FIG 5C**).
- Prepare the fresh-frozen allograft as described in the “General Principles” section. Start by making the allograft longer than the resected specimen.
- Make small cuts and recheck fit of the allograft.
- Check plain radiographs of the entire tibia in the operating room to assure proper fit of the allograft and confirm that a deformity is not being created.
- Select a plate that spans the intercalary defect and gets multiple points of fixation on both sides.
- Try to avoid open growth plates. If possible, consider compression plating across the host-allograft junctions. Be careful, too much compression and placement of cortical screws through a poorly contoured plate can lead to a fractured allograft.
- Hybrid fixation with locking screws is beneficial in short segments. Locking screws are also preferred on the allograft side as it minimizes risk of fracture (**TECH FIG 5D**).
- Only use enough screws on the allograft side to eliminate gross motion at the host-allograft junction. Too many screws can weaken the allograft.⁴
- A small second plate can be used to improve rotational strength if that is a concern.
- Closure is often primary. If there is notable skin loss, free tissue transfer may be needed.
- Patients are placed in a short leg splint. They are usually nonweight bearing for approximately six months. Partial progressive weight bearing is then started.

TECH FIG 5 • **A.** Illustration of the anteromedial incision for intercalary resection of the distal tibial diaphysis. **B.** Bone defect after resection of the distal tibia bone tumor. **C.** Length measurement of the resected segment of distal tibia. **D.** Spanning plate with hybrid internal fixation across the fresh-frozen intercalary allograft used to reconstruct the bone defect after tumor resection.

PEARLS AND PITFALLS

Imaging

- MRI scans are performed with and without contrast and done as a “tumor protocol.” Tumor protocol at our institution represents T1 axial, T2 fat-suppressed, and T1 fat-suppressed pre- and postcontrast

	images.
Localization	■ There are many small bones and joints in the foot and ankle. It is helpful to use intraoperative fluoroscopy to assure incisions are appropriately placed.
Biopsy	■ The oncologic approach to biopsy should be in-line with the incision necessary to perform a wide resection of the tumor.
Frozen section	■ Bone is too hard for frozen section processing. If sending a bone sample for frozen section, ask the pathologist to do a “touch prep” to examine cells inside the bone sample.
Implant selection	■ Future imaging will be needed to assess healing and look for recurrent tumor. Use of titanium implants can limit artifact on future MRI and CT scans. This benefit should be weighed against the need for a durable implant. New carbon implants may provide both strength and limited artifact on imaging.
Healing	■ Healing at the host-allograft junction can be augmented by step-cuts that increase the surface contact area between the two sides. Using microsurgery, vascularized bone, most commonly the fibula, can be set at the junction to aid healing and improve bone strength.

POSTOPERATIVE CARE

- Please see individual sections under “Techniques.”
- In all cases, patients are initially placed in a short leg splint and instructed to elevate the lower extremity at or above heart level for soft tissue rest.
- Structural fresh-frozen allograft used to fill defects in the lower extremity generally needs 6 months of nonweight bearing followed by partial progressive weight bearing to achieve full weight bearing over 4 to 6 weeks.
- Radiographs are done at 6 weeks and 3 months after surgery and then every 3 months for the first 2 years.
- Any mention of acutely worsened pain should trigger an assessment for infection and fracture.

OUTCOMES

- Very few studies have looked at outcomes of tumors about the foot and ankle, likely due to their rare incidence.
- Benign bone tumors of the foot and ankle are 3 to 4 times more frequently encountered than malignant bone tumors.^{5,6}
- In patients with malignant bone tumors of the foot, one center reported that

half were treated with some form of amputation.⁵

- A single-institution study found that the overall and disease-free survival rate at 9 years was 65% and 40%, respectively, for both benign and malignant bone and soft tissue tumors of the foot and ankle.⁶

COMPLICATIONS

- Leg length discrepancy: May develop from early physeal arrest. Two centimeters or less is well tolerated with a shoe lift. Anticipating this problem allows the surgeon to shut down the contralateral physis.
- Fracture: Fresh-frozen cortical allograft does not fully vascularize. The implant spanning the allograft will be needed for load-sharing forever and should not be removed. It is wise to restrict cutting and pivoting sports and activities.
- Nonunion: Allograft-host bone junctions can be slow to heal, especially at diaphyseal-diaphyseal junctions. Additional surgery to place cancellous autograft at the junction may be needed.
- Infection: Poor soft tissue coverage and lack of blood supply to bulk cortical allografts puts the surgical site at risk of infection. Generally, patients are maintained on oral antibiotics for three months after surgery. Infected allograft needs to be removed to clear the infection.
- Local recurrence: The surgeon should follow the patient for 5 years for high-grade and 10 years for low-grade malignancies to assess for local recurrence. MRI is generally the imaging modality of choice. The first postoperative scan is performed 3 months after surgery and serves as a baseline for future comparison.

Debridement of Soft Tissue Infections of the Foot and Ankle

9

CHAPTER

Hunter S. Oliver-Allen, Michael Holland, and Scott L. Hansen

DEFINITION

- Soft tissue infections of the lower leg and foot include a spectrum of severity from superficial cellulitis to rapidly progressive necrotizing fasciitis.
- Soft tissue infections of the foot and ankle can involve skin, subcutaneous tissue, fascia, muscle, ligaments, tendons, joints, and around the nails.
- Secondary infections can be due to peripheral vascular disease (PVD), diabetes, metabolic conditions, and immunocompromised patients.
- Infections of the foot and ankle are often categorized into three groups: soft tissue infections, bone infections, and diabetic infections.
- Infections can be further characterized into nonpurulent (cellulitis and erysipelas), purulent (abscess), necrotizing soft tissue infections (NSTI) (including necrotizing cellulitis, myositis, and fasciitis) as well as tendonitis and septic arthritis.
- Immediate goal is to treat and control the infection.
- Long-term goal is for limb salvage, preserve limb function, and decrease risk for amputation.
- Infections are most commonly caused by bacteria, however can also be due to viral, fungal, or mycobacteria.
- Some may respond to treatment with topical, oral, or intravenous antibiotics alone, while others will require surgical debridement of devitalized tissue.
- Typically present as painful lesions with skin changes invariably present, with or without involvement of deeper tissues.

ANATOMY

- The lower leg, ankle, and foot comprise 28 bones.
- Soft tissues include muscles that are divided into anatomically distinct compartments in both the lower leg and the foot (**FIG 1**).
- The four compartments of the lower leg include the anterior, lateral, superficial posterior, and deep posterior divided by fascia.
- The nine compartments of the foot include the calcaneal—communicating with the deep posterior compartment of the leg, superficial, medial, lateral, adductor, and four interosseous.
- The primary neurovascular structures include the anterior tibial, peroneal, and posterior tibial arteries and paired veins; superficial peroneal, deep peroneal, tibial, saphenous, and sural nerves; and greater and lesser saphenous veins in the superficial tissues.
- Plantar surface is composed of thick glabrous epidermis and dermis, and a subcutaneous layer with vertical fibrous septae, densely adhering it to the plantar fascia and periosteum.

FIG 1 • Cross section of the leg showing the compartments. (From Pansky B, Gest TR. Lower limbs. In: *Lippincott's Concise Illustrated Anatomy: Back, Upper Limb, and Lower Limb*. Vol. 1. Baltimore, MD: Wolters Kluwer; 2012:198.)

PATHOGENESIS

- Infections result from breakdown of natural defenses in skin such as with trauma or open wound and invasion of resident skin flora or environmental pathogens.¹
- Patients with neuropathy and vascular disease and are immunocompromised have increased risk of infection.¹
- Group A beta-hemolytic streptococcus is the most common and second most common is *Staphylococcus aureus*.
- Infections are also commonly polymicrobial, especially in diabetic patients.
- NSTI result from bacterial invasion and subsequent angiothrombosis decreasing blood supply causing tissue necrosis They are classified into two groups:²
 - Type I is a polymicrobial infection consisting of anaerobic bacteria and aerobic bacteria.
 - Type II is monomicrobial infections typically of group A streptococcus or other beta-hemolytic streptococcus alone or with other pathogens.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient's initial complaint is typically of pain and swelling at site of infection. They may also notice changes in skin color and drainage of fluid. There may be a history of antecedent trauma.
- Systemic symptoms such as fevers, chills, malaise may not be present early in the disease but indicate an immune response to the infection.
- Past medical history of diabetes mellitus, vascular disease, immunodeficiency, heart failure, cirrhosis, or prior surgery may predispose to infection.
- Physical exam may reveal erythema, swelling, tenderness, warmth, fluctuance, visible drainage, and eschar.
- Open wounds may be present with exposed subcutaneous fat, muscle, fascia, or bone.
- Pain out of proportion to physical exam findings or crepitus are concerning physical exam findings for necrotizing fasciitis.

IMAGING

- Despite its inability to well characterize fluid collections, standard multiple view radiographs are the first initial test to identify any bony injury or radiopaque foreign bodies as well as gas from anaerobic bacteria. Subtle soft

tissue changes may also be demonstrated but are harder to appreciate by the untrained examiner.

- Ultrasonography may show cobble stoning of the subcutaneous tissues, which is indicative of edema. Discrete, hypoechoic fluid collections may also be identified. For patients with isolated abscesses, please see the chapter on drainage of abscesses of foot and ankle.
- Cross-sectional imaging with CT or MRI may better evaluate the extremity to determine the extent of infection.¹

DIFFERENTIAL DIAGNOSIS

- Cellulitis
- Abscess
- Necrotizing fasciitis
- Plantar fasciitis
- Gout
- Skin cancer
- Venous stasis ulcer or dermatitis
- Impetigo
- Erysipelas

NONOPERATIVE MANAGEMENT

- Simple infections such as folliculitis or impetigo may improve with topical antibiotics alone.
- Cellulitis and more superficial infections require oral or intravenous antibiotics.
- Infected open wounds without burden of necrotic tissue may be treated with local wound care and antibiotics with careful monitoring for clinical worsening in poor surgical candidates.

SURGICAL MANAGEMENT

- The goal of surgery is to identify and debride all nonviable tissue, and a planned second look operation may be considered in severe infections where debridement is limited by critical structures.

Preoperative Planning

- In patients who are hemodynamically unstable or with suspected necrotizing infection, empiric antibiotic therapy should be ordered while drawing blood

cultures and should not be delayed for wound cultures.

- In patients who are otherwise stable, consider deferring antibiotics until wound cultures have been obtained.
- If hardware is present, consider need for removal with orthopedic surgery consultation, as well as need for bony debridement.
- Ensure medical comorbidities are addressed. Patients with infected wounds due to vascular ulcers may require preoperative revascularization. Diabetics should have tight glycemic control.
- Ensure appropriate laboratory investigations are obtained including complete blood count, basic metabolic panel, C-reactive protein, sedimentation rate, and blood cultures.
- Antibiotic selection should cover gram-positive organisms with MRSA coverage, and due to prevalence of gram-negative organisms in foot infections, gram-negative coverage should also be provided while awaiting culture results.

Positioning

- Supine position is usually sufficient for exposure.

TECHNIQUES

■ Debridement of Soft Tissue Infections

- Identify the affected area of the leg or foot and prep well beyond the border with healthy tissue (**TECH FIG 1A**).
- Identify necrotic or nonviable tissue and sharply debride without the use of cautery.
 - Avoiding cautery will allow using the presence of bleeding to guide when sufficient debridement has been performed.
- Necrotic tissue is picked up with forceps and trimmed with curved mayo scissors, Metzenbaum scissors for finer tissue, or scalpel.
- Tissue may be sent to pathology and microbiology for culture and Gram stain.
- Presence of tunneling or disruption of fascial planes should be examined to identify necrotizing fasciitis.
- Probe the wound for any areas of tunneling. Areas of tunneling with fascial

disruption and/or presence of “dishwater-” appearing fluid raises concern for presence of necrotizing fasciitis.

- If tunneling found, most overlying tissue should be opened to explore extent of infection, debride overlying tissue that is nonviable.
- Irrigate the cavity with at least 3 L of saline, which is easily done with cysto tubing (**TECH FIG 1B**).
- Obtain hemostasis with electrocautery.
- Pack the open wound with surgical packing.
- Consider ultimate reconstructive goal, including healing by secondary intention with wound care, wound Vacuum-assisted closure (VAC), skin grafting, local flap, or free flap (**TECH FIG 1C**).

TECH FIG 1 • **A.** Infected lateral malleolar wound after trauma. **B.** Debridement with high-pressure water. **C.** Healed wound with split-thickness skin graft.

PEARLS AND PITFALLS

Preoperative workup

- Failure to obtain blood cultures
- Failure to identify patients needing revascularization before making larger wound
- Delaying antibiotic therapy in severe infections
- Nutritional optimization

Technique

- Incomplete debridement resulting in need for additional surgery
- Incompletely exploring extent of wound/tunneling
- Use copious irrigation

Postoperative

- Placing wound VAC on infected wound

POSTOPERATIVE CARE

- Continue broad spectrum antibiotics while awaiting culture speciation
- Continue local wound care with at least twice daily dressing changes until wound is confirmed to be clear of infection, afterward specialty dressings or wound VAC may be applied which may be changed less frequently.
- Silver sulfadiazine or other silver impregnated dressings controls both bacterial growth and facilitates wound healing.
- Continue to optimize medical comorbidities and smoking cessation.
- Allow for at least passive range of motion exercises if weight-bearing surface is affected.
- Elevation of the extremity and pressure off-loading.

COMPLICATIONS

- Persistent infection
- Missed diagnosis of necrotizing infection
- Injury to neurovascular structures
- Hematoma

10 Debridement of Infected Bone of the Foot and Ankle

CHAPTER

Michael Holland and Scott L. Hansen

DEFINITION

- Osteomyelitis of the foot and ankle is defined by bacterial or less commonly fungal infection of bones of the lower third of the leg and foot.
- Spectrum of severity can range from chronic, indolent infections to acute, suppurative infections resulting in sepsis.
- Often resulting from existing soft tissue wound extending deep to underlying bone; however, seeding (eg, from bacteremia), direct inoculation (eg, trauma, puncture wounds), or healing of prior soft tissue defects can result in isolated osteomyelitis in the absence of soft tissue signs or symptoms.
- Frequently associated with hardware and prior fractures necessitating removal or replacement of hardware.
- The management of acute osteomyelitis is primarily medical, whereas the management of chronic osteomyelitis is mainly surgical in combination with antibiotic therapy.¹

ANATOMY

- The ankle is formed by the distal aspect of the tibia (medial) and fibula (lateral) articulating with the talus of the foot.
- The foot is composed of 26 bones functionally homologous to bones of the hand and wrist.
- The hindfoot is composed of the talus, which is seated on the calcaneus.
- The midfoot articulates with the bones of the hindfoot and is composed of the cuboid navicular and three cuneiform bones (medial, intermediate, and lateral).
- The forefoot is composed of the 5 metatarsal bones and 14 phalanges.
- Two sesamoid bones underlying the first toe metatarsal phalangeal joint also

are present in adults, with infrequently found accessory sesamoid bones at other joints.²

PATHOGENESIS

- Infection most often arises from soft tissue wounds, open fractures, complications from orthopedic reduction of closed fractures, hematogenous seeding from bacteremia or endocarditis, or inoculation from trauma

PATIENT HISTORY AND PHYSICAL FINDINGS

- History of diabetes mellitus, vascular insufficiency, venous hypertension, peripheral neuropathy, immunodeficiency, prior fracture, presence of hardware, prior surgery, and prior podiatric procedures are important to identify preoperatively in order to determine whether or not adjuvant therapy may be beneficial to precede operative intervention.
- Diminished sensation, paresthesias, and claudication are symptoms that may indicate the presence of these above comorbidities.
- Presence of open wounds with or without visible bone, erythema, fluctuance, and bony tenderness can indicate active infection.
- Decreased Semmes-Weinstein monofilament test, prior scars, palpable hardware, and venous ulceration are physical exam findings that may indicate higher-risk populations for developing osteomyelitis.

IMAGING

- Three-view plain radiographs of the foot and ankle are the first test to order, and will help give clear definition of bony anatomy, presence of hardware or radiopaque foreign bodies, and can detect subtle changes of osteomyelitis as early as 10 to 14 days but typically requires 3 weeks of active infection before changes will be found.³
 - Periosteal reaction (**FIG 1A**), lytic lesions, endosteal scalloping, loss of bone density, or trabecular architecture are findings indicative of osteomyelitis.⁴
- CT scan is useful for demonstrating extent of osteomyelitis and may detect radiologic changes earlier than plain radiographs; however, sensitivity is limited at around 67%⁵ and may have findings obscured by hardware artifact. Utility may be found in ability to evaluate extent of disease and to create three-dimensional reformats for reconstructive planning.
- MRI is the most sensitive and specific modality for diagnosis of osteomyelitis, as early as 3 to 5 days (**FIG 1B**).^{6,7}

FIG 1 • A. Radiograph of the right foot demonstrating periosteal reaction of the calcaneus indicating osteomyelitis. **B.** Corresponding MRI of the right foot demonstrating the extent of calcaneus osteomyelitis.

DIFFERENTIAL DIAGNOSIS

- Gout
- Cellulitis
- Plantar fasciitis
- Sickle cell anemia
- Neoplasm (primary or metastasis)

NONOPERATIVE MANAGEMENT

- Acute osteomyelitis without abscess or necrotic component can frequently be treated with isolated intravenous antibiotic therapy for a duration of at least 6 weeks. However, if nonoperative management fails, operative management is indicated.

SURGICAL MANAGEMENT

- Surgical debridement should always be considered and is mandatory for osteomyelitis with any necrotic component and, in combination with antibiotic therapy, is the mainstay of treatment for chronic osteomyelitis.

Preoperative Planning

- Identify need for glucose control, preoperative revascularization, smoking cessation, nutrition optimization, initiation of antiretroviral therapy, address patients ultimate reconstructive goal (eg, flap vs amputation).

- Coordinate with orthopedic surgeon if hardware is in place in order to determine plan for replacement with antibiotic spacer or removal.
- Consider orthopedic surgery consult if large amount of debridement is expected with possible destabilization of ankle joint or foot requiring spanning ex-fix or other temporary stabilization.
- Obtain infectious disease consultation for antibiotic selection and duration.
- A second look procedure should be anticipated and discussed with patient.
- Laboratory studies including complete blood count, sedimentation rate, C-reactive protein, metabolic profile, and blood cultures should be obtained and trended throughout therapy.

Positioning

- Place patient in supine position.
- Prep affected extremity from toes to groin with Betadine.
- Apply either lower extremity drape or split sheet to create sterile field.

Approach

- Principles of therapy include wide debridement, stabilization of remaining bony architecture, culture-guided antimicrobial therapy, and reconstruction of resultant bony defects.⁸

TECHNIQUES

■ Wide Debridement of Bone Infection

- If a wound is present with exposed bone (**TECH FIG 1A**), the wound edges are debrided sharply until healthy, bleeding tissue is reached (**TECH FIG 1B**).
- The underlying bone is inspected for viability.
- Any soft or necrotic bone must be removed with rongeur, curette, or osteotome, until healthy, viable bone is reached (**TECH FIG 1C,D**).
 - If hardware is present, it must also be removed at this time.
- Removed bone is sent to pathology and microbiology for culture and Gram stain.
- The resultant defect is examined for viability. Any remaining nonviable

tissue must be removed to prevent reinfecting compromised bone.

- The wound is irrigated copiously with at least 3 L of saline.
- Any dead space must be obliterated with antibiotic beads, cement, or soft tissue to prevent fluid accumulation.
- Bony stabilization can be further provided with plating, screws, or external fixation.
- A sterile, temporary dressing may be applied if second look is anticipated.
- After final debridement, soft tissue coverage must be applied by primary closure, local flap, or free flap.

TECH FIG 1 • **A.** Medial malleolar chronic wound with underlying bone involvement. **B.** After wound care, there is no significant change. **C.** Wound after soft tissue debridement. **D.** Wound after debridement of infected bone.

PEARLS AND PITFALLS

Preoperative planning

- Lack of patient optimization resulting in poor wound healing.
- Lack of plan with orthopedic surgeon for need for removal of hardware, stabilization.
- Not considering patient preferences for early amputation and reconstructive goals.
- 6-week antibiotics.
- Premature, early weight bearing and subsequent fracture.

Technique

- Not performing wide enough debridement to reach healthy margins.
- Not taking intraoperative cultures for culture-guided therapy.

- Not taking a second look.

Postoperative

- Inadequate antibiotic duration, failure to follow culture-directed therapy.

POSTOPERATIVE CARE

- The patient is continued on antibiotics that may be narrowed when culture data return.
- Laboratory values are checked every few days to monitor for response to treatment.
- Postoperative radiographs are obtained to document degree of bony resection.
- Infectious disease consultation is considered if not already obtained.
- The patient is allowed to work with physical therapy but is kept nonweight bearing until final orthopedic reconstruction is completed or stability determined to be sufficient. If soft tissue reconstruction performed, positioning restrictions may vary depending on appearance of flaps.

OUTCOMES

- Patients frequently require multiple surgeries for adequate debridement to viable tissue.
- With adequate debridement, need for subsequent amputation has been reported to be around 18%, minor 11.7% and major 6.3%.⁹
- Long-term limb salvage (avoiding need for major amputation) with surgical management is around 82%.⁹
- Persistent infection can be as high as 36% after debridement, underscoring need for adequate debridement of all nonviable tissue.¹⁰
- Overall perioperative mortality has been reported to be 1.6%¹¹

COMPLICATIONS

- Persistent infection
- Fracture
- Minor amputation
- Major amputation

11 Bony Reconstruction of Foot and Ankle (Bone Grafts)

CHAPTER

Kenneth J. Hunt and Loretta Chou

INTRODUCTION

- Recent decades have witnessed a dramatic increase in available bone graft harvest techniques, bone graft substitutes, and orthobiologic technologies. Despite the extensive availability and marketing of bone graft substitutes, and their purported advantages, autogenous bone graft remains the standard for augmenting healing during arthrodesis and nonunion surgery.
- Autograft bone is the only naturally occurring material purported to possess osteoconductive, osteoinductive, and osteogenic properties. Still, the use of bone grafts in orthopedic surgery has given rise to a multibillion dollar industry but has by no means eradicated nonunions in foot and ankle surgery.^{1,2} This chapter will discuss current bone grafting techniques and technologies for foot and ankle procedures in the context of the most common conditions and patient risk factors requiring augmentation for effective healing.

DEFINITION

- Bone grafts in the foot and ankle are most commonly utilized for three indications: (a) increase the union rate for arthrodesis in revisions or joints with a known propensity for nonunion, (b) increase union rate for nonunited fractures, and (c) replace or add bone structure due to chronic or acute bone loss. The focus of this chapter is bone grafting techniques to illustrate these three indications. We include some specific, common foot pathology that requires bone grafting, but an inclusive review of foot and ankle pathologies and disease processes is outside of the scope of this chapter.
- By far, the most common use of bone graft in the foot and ankle is to aid in healing for joint arthrodesis. The degeneration of joints requiring fusion can

occur as a result of a number of disease processes, including post-traumatic arthritis, degenerative joint disease (DJD), posterior tibial tendon insufficiency, trauma, congenital deformity, inflammatory or crystalline arthropathy, Charcot neuropathy, diabetes, avascular necrosis, tumor, and many other causes.

- Bone graft is generally incorporated to aid in healing when the risk of nonunion is unacceptably high. This is the case in patients who might have a suboptimal biologic healing response, including those with a history of smoking, diabetes, neuropathy, obesity, or a history of nonunion.³⁻⁵
- The procedures in the foot and ankle that most commonly involve bone graft application include ankle, subtalar (ST), tibiotalarcalcaneal (TTC), triple, tibio calcaneal (TC), talonavicular (TN), calcaneocuboid (CC), naviculocuneiform (NC), and tarsometatarsal (TMT) arthrodesis, and most nonunion repairs. Due to the paucity and inconsistency of literature on the topic, the decision to use bone graft, and which type or material to use (ie, cancellous vs structural, harvest site, autograft vs allograft, bone graft substitutes, etc.), is dependent upon a host of patient factors and surgeon experience.
- Generally speaking, cancellous autograft generally has a higher surface area and greater content of growth factors and remains the standard for its ability to induce more new bone formation than cortical (ie, structural) autograft or allografts.⁶ Structural autograft is often required when significant bone loss or deformity is present, as a means of restoring length, height, and/or alignment. The fast-growing arsenal of “orthobiologics” as substitutes for autograft are purported to rival autograft in terms of timing and rate of healing, without the morbidity of autograft harvest.

ANATOMY

- The foot and ankle is composed of 28 bones. There are multiple joints, muscles, tendons, and ligaments. The foot can be divided into the medial and lateral columns. The medial column includes the talus, navicular, cuneiforms, and medial three metatarsals. The lateral column is made up of the calcaneus, cuboid, and lateral two metatarsals. Any injury, deformity, or defect can result in length alterations or stiffness in one or more columns of the foot. This can lead to pain, imbalance, and problems with weight bearing on a foot that is not plantigrade, unstable, or painful.
- The ankle joint allows for most of the extension and flexion. The subtalar joint provides inversion and eversion, whereas the transverse tarsal joint

(talonavicular and calcaneal cuboid) gives adduction and abduction.

- The foot and ankle is responsible for gait. The heel is the first point of contact in the normal gait cycle. As the foot rolls forward, the foot changes from a flexible valgus position to a rigid varus position for push off.
- The anatomy of the iliac crest, for the purposes of graft harvest discussed herein, is fairly easy to identify and superficial. The graft harvests described below are generally harvested from 2 to 4 cm above the anterior superior iliac spine (ASIS). The crest at this location can usually be palpated. Keeping the incision and dissection at least 2 cm proximal to the ASIS to avoid injury to the lateral femoral cutaneous nerve.

PATHOGENESIS

- The foot and ankle are the most peripheral structures in the body and are dependent during most physical activities. As a result, the foot and ankle are at higher risk of peripheral neuropathy, peripheral vascular disease, and other contributors to delayed or nonhealing of fusions or fracture fixation.
- The weight-bearing role of the foot and the complexity of biomechanics for normal foot and ankle function place many regions of the foot and ankle at higher risk for abnormal loading, further contributing to delayed- or nonunion of fractures, arthrodesis, or osteotomies.
- Patient risk factors known to contribute to nonhealing of bone include smoking, diabetes, age and osteoporosis, peripheral vascular disease, neuropathy, noncompliance, infection, and soft tissue injury.⁴

NATURAL HISTORY

- The disorders of the foot and ankle are broad and significant and include trauma, arthritis, congenital, acquired, sports injuries, and degenerative conditions. With severe deformities or trauma, structural loss or nonhealing of fractures or fusions frequently lead to worsening of the disorder and pain and function, over time. Reconstructive operations may be required to repair such problems. In cases where there is need to add structural bone, or add biology, bone grafting procedures are commonly considered.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history is essential preoperatively. Patients are asked about injuries, chronicity, comorbidities, previous operations, and nonoperative treatment. Also, the patient's occupation and social situation are important considerations.

- Medical history should be considered when determining risk factors and the best bone graft to use. Social history is also important because patients may have particular traditions and beliefs governing whether autograft or allograft materials are acceptable. The beliefs should, and generally can, be respected during development of a treatment plan.
- The physical examination takes place with the patient undressed from the knees to the toes. Gait is evaluated, as well as the skin, noting edema, scars, erythema, masses, and bony deformities. The neurovascular status is carefully examined. Evaluating potential graft sites is also important.
- The foot and ankle examination can help guide surgical approach and counseling. Incisions should be made where soft tissue disruption, particularly of the well-vascularized periosteum, can be minimized. Old incisions should be incorporated whenever possible, especially when the procedure was recent.

IMAGING

- Most nonunions and malunions of fractures, fusions, and osteotomies can be diagnosed on plain radiographs (**FIG 1A**).
- For joints that are difficult to see on plain radiographs, or for complicated procedures with a large fixation construct, a CT scan is the best study to diagnose nonunion (**FIG 1B**).
- MRI scan plays little role in diagnosing nonunion but can be helpful to evaluate soft tissue structures, which may contribute to symptoms, and is a sensitive study for osteomyelitis.
- Nuclear medicine studies can aid in diagnosis of infection and osteomyelitis, which is a common contributor to nonhealing of bone (**FIG 2**).

FIG 1 • **A.** Plain lateral radiograph. **B.** Coronal and

sagittal CT scan images depicting a nonunion of ankle arthrodesis.

FIG 2 • Tagged WBC study demonstrating increased uptake in the left ankle compared to the right.

DIFFERENTIAL DIAGNOSIS

- Hypertrophic nonunion
- Oligotrophic nonunion
- Septic (infected) nonunion
- Malunion
- Avascular necrosis of bone
- Failure of fixation

NONOPERATIVE MANAGEMENT

- Nonoperative treatment for many foot and ankle disorders include activity modification, ambulatory aid, such as a cane or crutch. Physical therapy, brace, or orthotic device may be helpful. Oral medications can help reduce pain, although one must be aware of risks (eg, NSAIDs can contribute to delayed healing, narcotic analgesics carry risk of dependency).
- Severe deformities may be difficult to accommodate or fit into a brace, and surgical options should be considered.
- In general, if patients have persistent pain, dysfunction, problems working or participating in activities of daily living, or if there are risks to other structures or to the patient by continuing nonoperative management, surgery should be considered.

SURGICAL MANAGEMENT

- The decision to augment a fusion, osteotomy, or fracture with graft is dependent on many factors, including surgeon preference and experience. Grafts should, in general, be added to increase both the likelihood and the timing of bone union in cases where nonunion or delayed union is unacceptably high. Examples include revision cases and patients with risk factors outlined above.
- The authors prefer autograft iliac crest bone graft for most indications where there is high risk of nonunion. When structural grafts are necessary to span a cortical gap in bone, structural autograft from the iliac crest is generally sufficient for most procedures in the foot. Ankle and hindfoot bone loss often requires larger allografts, such as femoral head or fibular grafts.
- Orthobiologics can be used in lieu of, or in addition to, other graft materials, or to add a large dose of specific growth factors to the fusion site. Examples of such orthobiologic therapies include platelet-rich plasma (PRP), bone marrow aspirate concentrate (BMAC), bone morphogenetic proteins (BMP), and platelet-derived growth factor (PDGF). The enormous recent growth of the number of available biologic products carries with it a high cost and a paucity of data on safety, effectiveness, and clinical outcomes for many products, particularly compared to the iliac crest bone graft standard. It is the responsibility of the surgeon to judiciously utilize these products with a thorough knowledge of their mechanism(s) of action, approved indications, side effect profiles, and cost.
- The ultimate goal of any fusion, osteotomy, or fracture repair operation is bone healing, pain relief, and return to optimal function while avoiding complications, prolonged hospitalization, and revision operations. When a graft is selected, the surgeon must balance necessity, cost, comorbid factors, and risk and have a keen understanding of the selected graft(s) and technique.

Preoperative Planning

- Plain weight-bearing radiographs of the foot and/or ankle are necessary for complete evaluation (**FIG 3A**).
- Other imaging studies may be helpful. MRI may show extent of infection or the presence of avascular necrosis. CT scans confirm nonunion and show bone quality and structural bone loss, bony defects and deformities (**FIG 3B,C**).
- A complete evaluation of the skin and adjacent structures must be performed,

using radiographs when prudent. This should include the surgical site in the foot or ankle and any potential graft harvest site.

- A thorough discussion of risks and the postoperative course (which can be prolonged) should be had with the patient because compliance is vital to success.
- Ensure that appropriate equipment is available prior to starting the case. A good coring reamer is helpful for cancellous graft harvest (**FIG 4**). Osteotomes and retractors can help to expose and harvest cortical grafts. Allografts and biologics should be requested if these might be required.
- Plan for size and volume. It is important to estimate the amount of graft that will need to be harvested for a given procedure.

FIG 3 • **A.** Anteroposterior radiograph of nonunion of the first metatarsal. Axial (**B**) and sagittal (**C**) CT scans confirming the nonunion.

FIG 4 • Photograph illustrating components of a coring reamer setup for harvesting of autograft cancellous

bone graft. These include a coring reamer (7 mm diameter pictured here), a tipped trochar, and a T handle. Alternatively, power tools can be utilized with caution.

Positioning

- Most cases are performed with the patient in a supine position. This also facilitates graft harvest for most sites.
- The patient is typically positioned toward the edge of the bed to facilitate access to the foot and ankle.
- Generally, the autograft is harvested on the ipsilateral extremity. The graft site undergoes sterile preparation and draping along with the surgical extremity (**FIG 5A**).
- With distal lower extremity autografts, we advised that the patient have protected weight bearing in a cast or brace for the primary procedure, which also allows for healing of the harvest site.

Approach

- In the primary surgery setting, the decision to use bone graft is complex and based on the criteria outlined above. Once this decision is made, preoperative planning using available imaging should be undertaken. The surgical approach should ensure avoidance of injury to neurovascular structures and minimizing soft tissue disruption.
- For nonunion surgery, once a symptomatic nonunion is diagnosed and appropriate conservative measures have been taken toward healing and restoration of function, the use of bone graft is considered for revision surgical options.
- The approach for graft harvest is based on access to sufficient graft volume for the indication while avoiding large bone defects, bleeding, and injury to surrounding structures. We will specifically discuss and illustrate the four most common graft harvest sites for foot and ankle indications: the anterior iliac crest (structural and/or cancellous), the proximal tibia, and the calcaneal tuberosity.

FIG 5 • A,B. Prep and draping of iliac crest harvest site.

TECHNIQUES

■ Technique 1: Iliac Crest Autograft Harvest (Tricortical Structural)

- This technique is described in another chapter.
- Briefly, the ipsilateral hip is positioned with a well-padded bump. The area is draped after sterile surgical prep. An iodine barrier may be placed (**FIG 5B**).
- The incision site may be injected with lidocaine plus epinephrine to decrease bleeding.
- The anatomic landmarks are palpated, and a longitudinal incision is made along the iliac crest, starting 2 cm above the ASIS. The soft tissue is bluntly dissected until the periosteum is exposed.
- The periosteum is incised in line with the incision and the crest. Once bone is identified, subperiosteal dissection is performed to expose the crest. Great care must be taken to avoid penetration of the medial structures, especially if the inner table is required as part of the graft harvest.
- The size of the graft must be determined at this point, based on the defect size (**TECH FIG 1A,B**).
- Structural cortical or tricortical graft is removed with a saw or osteotomes (**TECH FIG 1C**).
- The graft is shaped to fit the defect (**TECH FIG 1D–F**). Additional

cancellous graft can be harvested from the crest if needed to fill gaps.

- Appropriate fixation is applied to stabilize the graft (**TECH FIG 1G,H**).
- Following harvest, the iliac crest area can be packed with Gelfoam and thrombin to aid in hemostasis.
- Allograft cancellous chips can be used to pack the harvest site. This can provide hemostasis as well as filling of the defect.
- Periosteum is closed after hemostasis is achieved followed by layered closure of the overlying soft tissue and skin (**TECH FIG 1I**)

TECH FIG 1 • **A.** Clinical photograph of bone defect requiring structural graft. **B.** Intraoperative fluoroscopic image showing the defect. **C.** Photograph of sagittal

saw used for iliac crest structural harvest. **D–F.** Harvesting of iliac crest bone segment measuring 1.3 cm, appropriate to fill defect. **G.** Anteroposterior. **H.** Lateral radiographs showing fixation of structural graft. **I.** Closure of iliac crest harvest site with absorbable subcuticular stitch.

■ **Technique 2: Iliac Crest Autograft Harvest (Cancellous)**

- This technique is for cases where cancellous autograft is indicated. The iliac crest cancellous bone contains the highest concentration of growth factors of the sites described in this chapter. Because it is a non–weight-bearing bone, this also mitigates risk of fracture postoperatively.
- As above, the ipsilateral hip is positioned with a well-padded bump. The area is draped after sterile surgical prep. An iodine barrier may be placed.
- The incision site may be injected with lidocaine plus epinephrine to decrease bleeding.
- The landmarks are palpated, and a small longitudinal incision is made along the iliac crest (usually about 1 cm in length), starting 2 cm above the ASIS. The soft tissue is bluntly dissected until the periosteum is exposed.
- The periosteum is incised in line with the incision and the crest. Once bone is identified, a trochar is used to create a defect in cortical bone (**TECH FIG 2A**).
- Next, a coring reamer is used to penetrate cortical bone penetrating up to 2 cm deep into the crest (**TECH FIG 2B–D**).
- Up to three passes (central, distal, proximal) can be made through one bone window. If additional graft is required, a second bone window should be created proximal to the end of the most proximal reaming pass.
- The periosteum is closed after hemostasis is achieved followed by layered closure of overlying soft tissue and skin.

TECH FIG 2 • **A.** Trochar and mallet used to create starting point in iliac crest for cancellous harvest. **B–D.** Coring reamer used to harvest iliac crest cancellous bone.

■ Technique 3: Proximal Tibia Autograft Harvest

- As with iliac crest autograft, it is ideal to obtain proximal tibia autograft from the ipsilateral tibia.
- The patient is placed in the supine position. A thigh tourniquet is used to create a bloodless field.
- A longitudinal incision is made medial to the tibia tubercle, about 1 cm (**TECH FIG 3A**).
- The periosteum is elevated, and the tibia metaphysis is identified. Small drill holes are made in a circular pattern.
- An osteotome is used to connect the drill holes, beveling the cortical window. The window is saved (**TECH FIG 3B**).
- Curettes or gouges are used to remove cancellous bone (**TECH FIG 3C,D**).
- The window is replaced and the wound closed in layers.

TECH FIG 3 • A. Incision for proximal tibia cancellous graft harvest. Marked V indicates tibial tubercle, **(B)** cortical window allowing access to cancellous bone of proximal tibia. **C.** Photograph illustrating curettage of cancellous bone from the proximal tibia, and **(D)** sample of typical harvest yield from proximal tibia.

■ **Technique 4: Calcaneal Autograft Harvest**

- Calcaneal bone graft is generally obtained from the ipsilateral calcaneus.
- In order to mitigate the risk of donor site fracture, this graft harvest is best selected in the setting of a procedure that will require a period of nonweight bearing.
- The patient is placed in the supine position. A calf or thigh tourniquet is used.
- Landmarks are identified first, including the tip of the calcaneal tuberosity, the peroneal tendons, and the distal fibula.
- A 2-cm oblique incision is made parallel and inferior to the peroneal tendons through the skin only, with blunt dissection down to bone and protection of the branches of the sural nerve (**TECH FIG 4A**).
- Elevation of the periosteum of the lateral calcaneus is performed to expose the cortical bone.
- A small diameter (7–8 mm) coring reamer is used to harvest cancellous bone from of the posterior tuberosity of the calcaneus (**TECH FIG 4B**). Multiple passes can be made through the same window, depending on volume need.
- The graft is collected in a small cup or receptacle such that appropriate volume can be assessed before discontinuing graft harvest (**TECH FIG 4C**).
- If required, additional bone can be curetted from the area, but use caution not to penetrate the far cortices.
- The skin is closed with 4-0 monofilament absorbable subcutaneous sutures, skin tape, and a period of nonweight bearing determined by the primary procedure.

TECH FIG 4 • A. Incision for calcaneal graft harvest. **B.** Coring reamer for calcaneal graft harvest. **C.** Resulting yield of calcaneal graft harvest.

■ Technique 5: Bone Marrow Aspirate Concentrate

In cases where structural graft is not necessary, but there is a desire to supplement biology with autograft marrow rich in stem cells, autograft bone marrow can be a valuable adjunct. This is usually harvested from the ipsilateral iliac crest, because this is the location with the greatest concentration of growth factors.⁷

- Bone marrow aspirate can be administered in three ways:
 - As an isolated graft injection
 - Combined with demineralized bone matrix (DBM)
 - Bone marrow aspirate concentration (BMAC) of growth factors
- Harvesting of bone marrow from the iliac crest:
 - The iliac crest undergoes sterile prep at the same time as the ipsilateral foot.
 - A separate sterile drape is used after prep, using sterile towels, followed by sterile iodoform drape. After the final sterile drape is placed, a small hole is cut in the drape and a second iodoform drape is used to seal the crest site (see **FIG 5**).
 - Bone marrow should be harvested just prior to its administration to optimize the viability of cells. A small incision is made with a no. 15 blade. It is essentially a puncture, just the width of the blade, providing room for the Jamshidi needle.
 - A Jamshidi needle is advanced to the iliac crest. Direct palpation assures that the needle is centered in the crest and directed centrally, between the

inner and outer tables (**TECH FIG 5A**). It is important to ensure that the inner table is not penetrated during harvest.

- Advance the needle about 1 to 2 cm into the crest and aspirate 2 cc. Then, redirect and advance the needle about 2 cm and withdraw an additional 2 cc. This can be repeated until sufficient volume has been harvested (**TECH FIG 5B**). The highest concentration of cells is in the first 2 cc at each location.⁸
- The BMA can be combined with DBM to create a cellular putty (**TECH FIG 5C**). This can be administered where small defects are present in joints and fractures with oligotrophic nonunions. This can be injected percutaneously in some cases to avoid disruption of blood supply.⁹
- Alternatively, larger volumes of bone marrow can be harvested and concentrated using a commercially available system and injected into the fracture or fusion site.¹⁰

TECH FIG 5 • **A.** Jamshidi needle placed in iliac crest through percutaneous incision. **B.** Syringe attaches to Jamshidi needle and 2 cc of iliac crest withdrawn. **C.** Bone marrow aspirate can be combined with DBM to create a cellular putty to fill small defects.

■ Technique 6: Concentrated Synthetic Growth Factors

There are many synthetic growth factors available to help augment healing of nonunions and at-risk procedures in the foot and ankle. Although a more thorough discussion is beyond the scope of this chapter, this is an important consideration for bone graft options.

More detailed descriptions can be found elsewhere in the literature.^{11–13}

- Examples of available bone graft substitutes along with a brief description include the following:
 - Bone morphogenetic protein (BMP-2)
 - Platelet-derived growth factor (PDGF)
 - Demineralized bone matrix (DBM)
 - Hydroxyapatite
- Limitations to utilization of these substances can include cost, FDA approval status (often limited for foot and ankle indications), and availability.

PEARLS AND PITFALLS

Hemostasis	■ Hemostasis must be obtained at the graft site prior to closure of skin in order to avoid bleeding, hematoma, and wound complications.
Controlling hemostasis	■ Lidocaine with epinephrine helps to control bleeding from the subcutaneous tissue. ■ Gelfoam and thrombin helps reduce postoperative bleeding.
Volume yield	■ The iliac crest bone graft harvest yields the greatest amount of cancellous graft. ■ Autograft from the proximal tibia may yield sufficient cancellous graft for many foot and ankle procedures.
Technique	■ Beveling the cortical window will prevent the window from falling into the tibia.
Wound closure	■ Closure with an absorbable monofilament subcuticular stitch and skin tape can provide a more cosmetic and less painful scar.
Plan ahead	■ Ensure that appropriate equipment for harvest and/or graft material is available for the procedure. ■ Estimate the volume and quality of graft required such that appropriate harvest sites and techniques can be utilized.

POSTOPERATIVE CARE

- Generally, the autograft is harvested from the ipsilateral limb, to facilitate protected weight bearing and frequently with a splint or cast. Crutches or knee

scooter devices are used in many of the procedures. The harvest site may heal in 6 to 12 weeks. Sutures may be removed at 2 weeks. Range of motion exercises may then begin at that time.

OUTCOMES

- There are a considerable number of reports in the literature addressing bone grafting techniques and their impact on fusion rates following reconstructive surgeries. Contributing factors include the breadth of procedures and diagnoses, the impact (or poor reporting) of patient factors, and inconsistent indications for bone grafting. Although most available data come from level IV and V data, some meaningful conclusions can be drawn.
- Lareau et al.¹⁴ reported a systematic review of the literature on bone grafting for the foot and ankle. While underscoring the need for more level I and II evidence to better guide our use of bone graft adjuvants during foot and ankle surgery, their pooled data demonstrated a trend toward favoring the use of cancellous autograft, structural autograft, or cancellous allograft over using no graft material during fusion surgery.¹⁴ They suggest that using no graft leads to nonunion rates of only about 10% (ie, a greater than 90% union rate), whereas the addition of cancellous autograft, structural autograft, or cancellous allograft reduced the nonunion rate by half.

COMPLICATIONS

- Complications from autograft from the iliac crest include infection, nerve injury, painful scar, nonunion, and pain. Harvest from the proximal and distal tibia or calcaneus may result in infection, numbness, and rarely fracture through the graft site. Superficial infections may be treated with local wound care and oral antibiotics. Rarely, the infection is deep, requiring surgical debridement and intravenous antibiotics.

12 Reconstruction of the Forefoot

CHAPTER

Rachel E. Hein and Scott T. Hollenbeck

DEFINITION

- The primary goal in forefoot reconstruction is to preserve function of the lower extremity. Given the unique bony and skin arrangements in the foot as well as the high functional demand for this area, an understanding of multiple reconstructive approaches is necessary.

ANATOMY

- The forefoot contains the distal third of the foot from the base of the metatarsals to the distal phalanges of the toes on both the plantar and dorsal surfaces of the foot.
- The plantar surface of the foot has highly specialized glabrous skin with a thick epidermis. Beneath the skin and subcutaneous tissue is the plantar aponeurosis, which is a thick fibrous band adherent to the skin. This resists shearing forces as it attaches to the skin via the retinaculum cutis ligaments distal to the metatarsals. In contrast, the dorsal skin of the forefoot is extremely thin and relatively mobile.
- The bones of the forefoot are somewhat analogous to the hand with the first toe containing only a distal and proximal phalanx. The second through the fifth toes have a middle phalanx. There are five metatarsal bones, which span from the midfoot bones (cuneiforms and cuboid) to the proximal phalanx of each digit.
- There are four separate plantar fascia compartments and one dorsal fascial compartment that are divided by intermuscular septa. These separate the intrinsic muscles of the foot.
- The medial and lateral compartments are the most relevant for reconstruction

as the muscles are most superficial and amenable to flap use. Of note, the medial compartment contains the abductor hallucis (AH) and flexor hallucis brevis (FHB) whereas the lateral compartment contains the abductor digiti minimi (ADM) (**FIG 1**).

- There are extrinsic and intrinsic muscles of the foot.
 - The extrinsic muscles originate in the leg and insert onto the bones of the foot.
 - The peroneus tendons insert onto the 5th metatarsal and allow for foot eversion.
 - The extensor digitorum longus (EDL) tendons insert onto an extensor mechanism of each of the lateral four digits.
 - The extensor hallucis longus (EHL) tendon has its own muscular unit and inserts onto the first phalanx.
 - In addition to the digit extending muscles, the foot may be brought into extension by the tibialis anterior (TA), which inserts onto the medial cuneiform/first metatarsal junction.
 - Preservation of at least one of these three systems is needed to prevent a functional footdrop. The digital flexors have a similar arrangement to the extensors, with the flexor digitorum longus (FDL) inserting onto each of the lateral four digits and the flexor hallucis longus (FHL) tendon inserting onto the first toe.
 - Plantar flexion is primarily driven by the Achilles mechanism of the heel, but digit flexors do have some importance as it pertains to the toe push off phase of the gait cycle.
 - The intrinsic muscles are contained in the compartments of the foot and primarily act on the toes.
 - The flexor digitorum brevis (FDB) occupies the central aspect of the superficial muscles of the plantar surface of the foot. There are two additional deep layers of muscles in the plantar foot that are not commonly used in reconstructive surgery.
 - Secondary action of intrinsic muscles includes maintaining posture and foot concavity.
 - The dorsal aspect of the foot is primarily made up of the extrinsic tendons, deeper intrinsic digit extensors, and still deeper interosseous muscles.
- The main vascular supply to the foot comes from the posterior tibial artery. The artery splits into the medial and lateral plantar arteries beneath the flexor retinaculum. These two arteries join at the base of the metatarsals to form the

deep plantar arch.

- The lateral plantar artery is the dominant artery supplying the fourth and fifth toes through metatarsal and then proper digital arteries.
- The medial artery supplies the first through third toes in a similar fashion. The dorsalis pedis artery supplies the dorsum of the foot and also gives terminal branches completing the plantar arch. For reconstructive purposes, the plantar intrinsic muscles of the foot are typically supplied via the medial and lateral plantar arteries (**FIG 2**).
- Cutaneous sensation to the forefoot is supplied via terminal branches of the sciatic nerve. The plantar surface of the forefoot sensation is mainly derived from the medial plantar nerve (tibial origin) and the lateral plantar nerves (tibial origin).
- The dorsal forefoot sensation is mainly derived from the superficial peroneal nerves (common peroneal origin) and the unique first web space distribution of the deep peroneal nerve (common peroneal, sciatic, L5 origin).
- Motor innervation of the intrinsic foot muscles is mainly through the medial and lateral plantar nerves¹ (see **FIG 2**).

FIG 1 • Sole of foot.

FIG 2 • A,B. Anatomy of the foot, vessels, and nerves.

PATHOGENESIS

- Traumatic foot injuries are typically associated with high-energy events. This may lead to extensive and complex wounds involving lacerations, contusions, skin degloving, open fractures, and severe crush injuries.
- Cancerous lesions may require extensive surgical resection and reconstruction within the foot. Many of these are amenable to isolated digit or ray amputation but some may require large skin resections on weight-bearing areas of the foot.
- Postsurgical complications following foot and ankle surgery may also present with complex problems involving necrotic skin, exposed tendons, colonized hardware and bony nonunion.
- Chronic vascular disease including venous stasis and peripheral vascular disease can be a cause of tissue loss within the forefoot. This should mainly be addressed by controlling the inciting factor. Amputation and debridement are often needed in these cases prior to any consideration of reconstruction.
- Diabetes is a major contributor to forefoot wounds and ulcers. Many of these patients have diabetic neuropathy and develop pressure-related ulcers over the

metatarsal heads. Prior to consideration of reconstruction, the patient's status should be optimized and nonsurgical options should be considered. This may include weight-bearing restrictions and/or use of shoe inserts to deflect pressure away from the affected area.²

NATURAL HISTORY

- The lower extremity is commonly involved in motor vehicle injuries, and this is the most common scenario requiring forefoot reconstruction. These are often complex injuries and may involve multiple levels of the lower extremity and multiple systems within the patient. Standard principles of trauma care must be followed. Once the patient has been stabilized, foot reconstruction may involve a multidisciplinary limb salvage team including plastic and orthopedic surgeons.
- A unique trauma scenario involving the forefoot is that related to lawn mower injuries and amputations. These are often isolated foot injuries but may be severe in nature.
- Replantation of amputated digits is not typically performed in the lower extremity.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Gait cycle and biomechanics
 - Reconstructive surgeons managing wounds of the foot should be familiar with the gait cycle as it pertains to functional outcomes. Classically, there are three cycles of the stance phase of ambulation including heel strike, midstance, and propulsion. This is followed by the noncontact swing phase.
 - For the purpose of forefoot injuries, it is important to note that high pressures occur during propulsion and include the final contact point at the first toe. Higher pressures and abnormal gait may lead to skin breakdown and development of wounds over the forefoot.³
- Evaluation of forefoot wounds
 - Initial evaluation of a patient with an acute traumatic injury to the foot includes assessment of the mechanism, energy, and contamination associated with the event. This often occurs during the initial washout and debridement of the wound. The associated soft tissue injury and underlying bony injury should be appreciated as well as the integrity of the vascular and neurologic systems within the foot.
 - Understanding a patient's underlying comorbidities as well as preinjury

functional status and work demands is also important.

- Doppler examination is useful to determine arterial perfusion as well as planning for operative intervention. However, severe edema may prevent accurate Doppler assessment, and additional angiographic studies may be required. Any presumed acute arterial injury warrants a vascular surgery consultation and subsequent evaluation for compartment syndrome.⁴
- Neurologic evaluation of the injured foot may be limited due to associated neuropraxia and tissue edema. Declaration of a nonsalvageable foot based on neurological injury should be deferred during the acute injury phase.
- For chronic wounds, duration of wound and measurements should be taken including length, width, and depth. Involvement of skin, dermis, fascia, muscle, tendon, and bone should be noted as well as any concurrent cellulitis. Photographs should be taken, and previous therapies should be noted. Gait analysis is also important in these patients as disease processes can affect weight bearing over the forefoot. Vascular and neurological status is also important to take into account.

IMAGING

- The physical exam will dictate the imaging studies needed when evaluating foot wounds. In the trauma setting, plain films are typically obtained first to rule out fractures. In some circumstances, a CT scan or MRI is obtained for better bony and ligamentous imaging. Angiography is typically reserved when evaluating more proximal injuries, but may be useful on certain occasions.
- Chronic infectious wounds such as diabetic ulcers and postoperative wound breakdown require plain films to rule out pathologic fractures and gas in the subcutaneous tissues along with MRI to rule out osteomyelitis. Bone biopsies are the standard, but MRI may help delineate operative management in these cases. Ankle-brachial indices and duplex arteriogram should be obtained to assess arterial insufficiency and need for possible vascular intervention.

DIFFERENTIAL DIAGNOSIS

- Traumatic
- Postsurgical
- Infectious
- Diabetic
- Acute arterial
- Venous ulceration

- Connective tissue disorder

NONOPERATIVE MANAGEMENT

- Traditionally, dressing changes are helpful for managing small superficial wounds through healing by secondary intent. Negative pressure wound therapy (NPWT) may also be used to achieve secondary healing or to prepare a complex wound bed for a skin graft or flap.
- Newer wound dressings have also aided in the treatment of open forefoot injuries including semipermeable dressings, hydrocolloids, and hydrogels. These new dressings can aid in chemical debridement as well as hydration of the wound. Additionally, synthetic products and xenograft products exist and may have some utility in managing these wounds. More data are needed to prove the clinical efficacy of these treatments.
- Hyperbaric oxygen (HBO) treatment may be used as an adjunct to traditional wound healing methods but remains somewhat unproven in its efficacy for foot wounds. HBO works by promoting angiogenesis and ultimately increasing the amount of vascularity in the wound bed, thereby promoting wound healing. It may be indicated in crush injuries, refractory osteomyelitis, and gas gangrene.

SURGICAL MANAGEMENT

Preoperative Planning

- Debridement remains one of the most important preoperative principles in lower extremity salvage. For an acute wound, it is important to perform serial debridement if necessary until all nonviable tissue has been removed. Chronic wounds should be serially debrided until negative cultures are obtained. Comorbidities should be managed for optimization.
- Once a decision has been made to proceed with reconstruction, the timing of intervention should be determined. Typically, this will be based on the underlying source of the wound.
 - In acute trauma settings, debridement and bony fixation should be complete. An understanding of vascular and nerve injury should be established. At this point, the extent of the reconstruction will be known and a proper approach may be determined.
 - The ideal window to operate on traumatic injuries is within the first week, if not sooner. Bacterial contamination and traumatic edema make reconstruction more difficult and warrant delay.

Positioning

- A modification of standard supine positioning is required for most procedures. For plantar defects, it is often best to place the patient in a lateral decubitus or possibly prone position. Of course the positioning will be influenced by the planned reconstruction. A thigh or calf tourniquet is often used during these procedures to optimize visualization. Bipolar cautery should be available when procedures involve deep structures near the neurovascular bundles.

Approach

- Reconstructive options for forefoot wounds include secondary closure, skin graft or skin substitute, local or random patterned flap, pedicled flap, or free flap with microvascular anastomosis.
- Function and aesthetics must be taken into account. For example, a split-thickness skin graft to a wound bed is not likely to be a durable option for a plantar defect. Likewise, a large bulky flap placed on the dorsal forefoot is likely to make shoe fitting difficult. The specific approach for each reconstructive option is listed below.
- *Delayed primary closure* is often difficult to perform secondary to refractory edema and minimal skin laxity of the foot.
- *Tissue expansion* is often not an option for the same reasons listed above.
- *Skin substitutes* have become popular in recent years and are used as dermal replacements in patients who would otherwise require flap reconstruction. A secondary skin graft is often needed. These products are directly applied to the wound bed after debridement.
- *Local random patterned flaps* are an option in patients with small foot wounds who may not be good free flap candidates. These flaps are inherently difficult to move in the foot.
- *Pedicled flaps* are useful in the forefoot due to rapid harvest and inset; however, for many of these flaps to reach the forefoot they must be based on unreliable distal perfusion. Another approach is to slide the flap with a component of plantar tissues in a V to Y pattern. These flaps can include both muscle and fasciocutaneous elements.
 - The reverse abductor digit minimi (ADM) flap is harvested along the lateral aspect of the plantar surface near the 5th metatarsal. The distally based flap and reverse based flap are useful for plantar forefoot wounds.
 - The reverse AH flap may be used for plantar defects of the forefoot. This muscle originates from the medial border of the calcaneus and inserts on the

base of the proximal phalanx of the great toe.

- The reverse FDB flap and the FDB based V-Y advancement flap are used in distal plantar surface wounds of the arch. For the reverse flap to be used, the dorsalis pedis and anterior tibialis must be intact as the medial plantar artery perforator is divided.
 - The toe fillet flap is a form of pedicled flap and is used after a toe amputation to cover a plantar- or volar-based wound associated with the effected digit.
 - The reverse dorsalis pedis fasciocutaneous flap can be designed up to 10 cm in size and is based on the dorsalis pedis artery. The pedicle of a standard dorsalis pedis flap is based on the dorsalis pedis artery; however, its reverse is based on the deep plantar arch and thus completeness of the arch must be assessed.
 - Reverse medial plantar artery flap: This flap contains the skin of the instep or non-weight bearing area of the plantar surface from the head of the first metatarsal to the navicular bone proximally.⁵⁻⁷
- *Free flaps* entail harvesting tissue from a different site along with its blood supply and transferring it to the recipient site. This requires a microvascular anastomosis. Both fasciocutaneous and muscle flaps work well on the forefoot and depend on goals of reconstruction.
- Important aspects of the approach for free flap reconstruction include choosing a donor flap that will easily cover the defect. If the flap is too small, the closure will be tight.
 - Vessel size needs to be considered to match the flap with the foot recipient vessels. Also, the vascular anastomosis needs to be performed outside of the zone of injury which may even be at or above the ankle. Finally, the flap must be of sufficient bulk to obliterate any underlying dead space.
 - Free flap choice: Considerations on choice of free flap include size of wound, defect composition, pedicle size and length, and state of wound. Location of wound also precludes itself to choice of flap. The foot may be broken into seven subunits, which have been established for functional and aesthetic reconstructive goals. With respect to the forefoot, there are four relevant subunits (**FIG 3**). Each has its own aesthetic and functional concerns with regards to reconstruction.

Subunit	Demands Tissue Needs	Optimal Flaps
1	Low functional, Moderate aesthetic: small, thin and pliable.	Radial forearm > lateral arm
2	High functional, Low aesthetic: durable and minimal bulk.	(*): Radial forearm > lateral arm > gracilis with STSG > ALT
3/4	Low functional, High aesthetic: smooth, thin and pliable	Radial forearm > ALT > scapular > latissimus dorsi
5	High functional Low aesthetic: durable and moderate bulk.	(*): ALT > gracilis with STSG > latissimus dorsi > scapular > lateral arm > radial forearm
6/7	Moderate functional, Moderate aesthetic: may vary from smooth, thin and pliable to Large and bulky.	Gracilis with STSG, latissimus dorsi, ALT, rectus abdominis, lateral arm, radial forearm, scapular

STSG: Split thickness skin graft
ALT: Anterolateral thigh
*: Nerve coaptation may be considered.

FIG 3 • Four separate views of foot and ankle demonstrating different aesthetic and functionally different subunits. There are four different relevant subunits of the forefoot. (Reprinted from Hollenbeck S, et al. Longitudinal outcomes and application of the subunit principle to 165 foot and ankle free tissue transfers. *Plast Reconstr Surg.* 2010;125(3):924-934, with permission.)

TECHNIQUES

■ Secondary Healing Using Regenerative Matrix

- Skin substitutes have become more popular in the recent years and are used in patients who may otherwise require flap reconstruction.
- Contraindications include exposed hardware; relative contraindications include exposed tendon or bone.
- Begin by obtaining adequate debridement. All nonviable tissue should be removed. Healthy bleeding tissue or bone should be visualized. If covering a chronic wound, ensure that negative cultures have been obtained (**TECH FIG 1A**).
- Apply the wound matrix to the exposed area generously. Similar principles to application of a skin graft applies and includes ensuring adequate contact of matrix to wound bed.
- After application, the matrix is fixated per surgeon preference including absorbable sutures such as chromic or staples that may be removed postoperatively. A hydrated dressing should be applied. This includes a negative pressure wound dressing or semipermeable colloid dressing. This remains in place for 1 to 4 weeks (**TECH FIG 1B**).
- Depending on the type of matrix applied, a bilayer may require removal around 4 weeks with the final result being total skin closure or a granulation bed that requires skin grafting (**TECH FIG 1C**)

TECH FIG 1 • A. The left foot with a full-thickness defect down to bone following elective orthopedic surgery. Adequate debridement is obtained to healthy bleeding tissue. **B.** After 4 weeks of application of regenerative matrix (porcine bladder elements), an appropriate dressing should be applied that obliterates the dead space and keeps the wound hydrated to encourage granulation. **C.** Six weeks postoperatively. Full closure with minimal eschar remains. Regenerative matrix may be sufficient for small wounds that would otherwise require flap coverage.

■ Reverse Fasciocutaneous Flap (Reverse First Dorsal Metatarsal Artery [1st DMTA] Flap)

- Begin by obtaining adequate debridement. All nonviable tissue should be removed. Healthy bleeding tissue or bone should be visualized. If covering a chronic wound, ensure that negative cultures have been obtained (**TECH FIG 2A**).

- A Doppler should be used to identify the first dorsal metatarsal artery on the dorsum of the foot. The flap is then designed around this using the measurements needed to fill the defect. The proximal extension of the flap is designed so that once rotated it will fit into the defect (**TECH FIG 2B**).
- Dissection begins around the marked flap, first beginning over the dorsal skin and continuing through the fascia exposing the underlying tendons. Care is taken to preserve the paratenon associated with the tendons (**TECH FIG 2C**).
- The flap is then rotated around the axis of the 1st DMTA, which is located typically underneath the first interosseous muscle and adjacent to the metatarsal bone. The flap can be kept as a peninsula or as an island (**TECH FIG 2D**).
- It is important to ensure that the inset is relatively tension free. The flap donor defect is covered with a split-thickness skin graft (**TECH FIG 2E**).⁹

TECH FIG 2 • A. Chronic dorsal great toe wound,

debrided back to healthy tissue. Negative cultures obtained. **B.** First dorsal metatarsal artery flap, marked and dissected to level tendon, keeping paratenon intact. Flap is undermined taking care to ensure the perforator is not inadvertently divided. **C.** Proximal end of flap is rotated 180 degrees to fill the defect. One must ensure a relatively tension-free closure. **D.** A split-thickness skin graft is harvested to fill the donor site. There is typically some venous congestion of the distal portion of the rotated flap; however, in our experience this has done well with time. **E.** Six weeks postoperatively with a completely healed wound and donor site.

■ Free Gracilis for Osteomyelitis

- The gracilis free flap may be used over the plantar surface of the forefoot in weight-bearing areas. It is a Mathes and Nahai II flap with its main blood supply from the medial circumflex artery off of the profunda femoral artery. The muscle itself is 30 cm long, 5 cm wide and 2 cm thick.
- The gracilis muscle is an excellent option for chronic defects of a weight-bearing area in association with osteomyelitis (**TECH FIG 3A**). Debridement should include all nonviable tissues and affected areas. Negative cultures should be obtained.
- For this type of defect (**TECH FIG 3B**), local types of closure are not an option. A free tissue transfer (gracilis) has been chosen.
- The dorsalis pedis artery is dissected proximally out of the zone of injury and is isolated. Attention is now turned to the donor site.
- For harvest, the patient is placed in supine and frog-leg position. A line is drawn from the medial pubic tubercle to the medial femoral condyle.
- The gracilis should include the proximal portion along with the length needed to obliterate the defect.
- Transfer and inset takes place (**TECH FIG 3C**) via the dorsalis pedis artery. Primary closure of the donor site is obtained, and a split-thickness skin graft is used to cover the newly inset flap. This provides stable coverage and good

shoe fitting (**TECH FIG 3D**).¹⁰

TECH FIG 3 • A. This patient suffered from chronic osteomyelitis of the first metatarsal head as a postoperative complication and eventually underwent ray amputation of the first toe as pictured. **B.** Debridement of entire affected segment and remaining metatarsal head and shaft. This has left the patient with a large defect that is not amenable to local types of closure. **C.** After inset of free gracilis. It is important that the tissue transfer obliterates dead space of the wound. Closure should be relatively tension free. **D.** Two months postoperatively. The patient has completely healed the wound and has an overall aesthetically pleasing result.

■ Free Flap for Distal Skin Defect

- The radial forearm free flap is the flap of choice for most forefoot reconstruction defects. This flap meets both the aesthetic and functional needs including being both thin and pliable. It varies in size and can be harvested from the wrist to the antecubital crease. This flap is primarily a

fasciocutaneous flap but may be harvested also as a myocutaneous or osteocutaneous. Its blood supply is the radial artery.

- In this example, free tissue transfer may be used in chronically infected wounds or in wounds with exposed hardware. This patient did not have a sizeable tissue defect and thus radial forearm flap was a great match due to pliability, coverage, and aesthetic result (**TECH FIG 4A**).
- First, obtain adequate debridement; in this patient debridement was conservative due to acute osteotomies with nonunion and exposed hardware.
- For harvest, the nondominant arm is typically utilized. An Allen's test is performed preoperatively to ensure that the palmar arch is intact.
- Doppler is utilized to identify the radial artery. A flap matching the size of the defect is marked with the radial most aspect over the radial artery.
- Dissection proceeds distally through skin, elevating fascia with the flap. Ensure to leave paratenon intact. The radial artery is dissected out proximally and ligated according to pedicle length need.
- The flap is then inset over the defect and anastomosed to the dorsalis pedis artery (**TECH FIG 4B**). Antibiotics are utilized due to exposed and presumed infected nature of the hardware. This will be kept for up to 6 weeks. Long-term coverage of the dorsal foot with a radial artery flap provides excellent contour (**TECH FIG 4C**).
- Donor site may be closed primarily depending on defect size and if tourniquet was used (**TECH FIG 4D**). If defect is large, split-thickness skin graft may be utilized.¹¹

TECH FIG 4 • A. This patient has exposed hardware after orthopedic procedure presumed to be infected. This was unable to be removed due to nonunion. The patient was taken to the operating room for proper debridement. **B.** Radial forearm free flap after anastomosis and inset. Good size and thickness match is noted. **C.** Defect 2 months postoperatively. The forefoot is well healed with no signs of exposed hardware or chronic infection. The patient remained on a course of IV antibiotics for 6 weeks. **D.** Donor site. The patient's donor site was amenable to primary closure due to the small size of the defect. The patient has completely healed donor site with good perfusion of the hand and no chronic paresthesias.

■ Free Flap For Mangled Foot—Latissimus

- Latissimus is one of the largest muscles in the body and is used for covering large defects. The muscle may be harvested up to 35 cm in size and may be used as a muscle or myocutaneous flap. This is a Mathes and Nahai type V flap with the main blood supply coming from the thoracodorsal artery and

vein.

- In this example, the patient suffered from a severe mangled foot after a crush injury. Acute debridement is performed in several stages along with external fixation. It is important to determine the viability of the surrounding tissue prior to reconstruction (**TECH FIG 5A**).
- The free latissimus is chosen for reconstruction. The patient is placed in a lateral decubitus position for both harvest and inset.
- The harvest site is prepared; in this case, the anterior tibial vessels are used and dissected out proximally out of the zone of injury.
- The latissimus is now harvested as a muscle flap in its usual fashion. The donor site may be closed primarily over a suction drain.
- The muscular flap is inset over the defect and anastomosed to the anterior tibial vessels, taking care to obliterate the dead space (**TECH FIG 5B**). A split-thickness skin graft is used to cover the muscular flap. A tension-free closure should be obtained.
- A muscle flap with a split-thickness skin graft may provide excellent durable long-term coverage of the dorsal and plantar foot allowing for ambulation (**TECH FIG 5C,D**).¹²

TECH FIG 5 • A. The right lower extremity after a severe crush and degloving injury. The patient undergoes external fixation along with adequate debridement performed in several days. **B.** After inset

and skin grafting of latissimus flap over mangled foot. External fixator still in place. **C.** Two months postoperatively with acceptable contour. Wound well healed. **D.** Six months postoperatively, fully healed and with great aesthetic result that will fit in shoe or prosthesis.

PEARLS AND PITFALLS

Function	■ Amputation may be a reasonable option for wounds involving the forefoot. However, there will be some degree of functional loss associated with disruption of the propulsion phase of the gait cycle.
Tendon coverage	■ Reconstruction of the forefoot may involve wounds that are associated with flexors or extensors of the ankle. Preservation of these insertion points may impact leg function significantly.
Local flaps	■ Local flaps may be limited in the foot as there is minimal skin laxity for advancing and rotating these flaps. Ideally, incisions should not be placed on the weight-bearing areas of the foot.
Flap options	■ Free flap choices can be guided by consideration of the defect location and functional demand of the area in combination with aesthetic considerations and shoe fitting requirements. Microvascular anastomosis should be performed out of the zone of injury. Secondary thinning may be required especially for bulky fasciocutaneous flaps.
Outcomes	■ Free flap failure in the foot and ankle may be as high as 10% and is often related to a tight skin closure or poor distal extremity perfusion. Success is measured in stable skin coverage, bony healing, painless ambulation, and shoe fitting.

POSTOPERATIVE CARE

- At the time of reconstruction, patients are typically placed in a posterior slab splint to minimize movement. A hole may be cut as a window to view the surgical site. This splint is typically kept until the patient begins transfers at which a formal splint will be applied.
- Leg elevation is an important aspect of foot reconstruction, especially in the

setting of trauma. A typical protocol for free flaps is strict bed rest and leg elevation until postoperative day 4. At this point, the patient may begin working with physical therapy for dangling the lower extremity during transfers for 5 minutes 3 times daily. Weight-bearing status is dictated by orthopedic restrictions. Activity and dependent positioning should progress over the next several weeks. At this point, a compression garment may be applied to help with edema. During this course, it is important to utilize a prophylactic anticoagulant dose to prevent venous thromboembolism.

- CAM boots are typically used to offload pressure from the forefoot as the patient begins weight bearing. Sutures are typically kept in place for 3 to 4 weeks, but should be removed prior to ambulation to prevent callus formation or postoperative ulceration.
- Range of motion exercises are typically initiated in the noninvolved joints immediately postoperatively to prevent stiffness. Exercises in involved joints of reconstruction are begun somewhere between 5 days and 2 weeks.
- Postoperative follow-up should be frequent and consistent. This should involve a multidisciplinary team including plastic surgery, orthopedics, vascular surgery, podiatry, physical therapy, and wound care as needed. Many centers have limb salvage programs that incorporate these aspects of care for their patients.

OUTCOMES

- The majority of patients undergoing flap reconstruction with local or free flap transfer have a successful recovery. Free flap viability rates have been quoted to be 90% to 93% in lower extremity reconstruction. In those with primary flap failure, treatment consists of debridement and wound care with consideration for further reconstruction. Patients that experience flap failure are at increased risk for amputation.
- Some patients will have long-term wound healing issues, with ulceration around the site of flap inset. This may occur anywhere from months to years after surgery and typically occurs on the weight-bearing surfaces of the foot at the flap interface.
- Secondary procedures are common in forefoot reconstruction and are most commonly associated with debulking procedures, especially when free tissue transfer is performed. Instability or nonunion is infrequently seen in the forefoot.
- Amputation may be indicated in the primary setting or after reconstruction

failure. Functional loss of an amputation needs to be weighed against morbidity of limb salvage. For the forefoot, options include isolated digit amputation, ray amputation, or transmetatarsal amputation. For those with vascular disease or open fractures, a higher level of amputation may be required.^{8,12}

COMPLICATIONS

- Given the high risk nature of the patient population, complications can occur. Acute complications may be related to poor perfusion within the flap. This may occur when distally based flaps are used or when free flaps become compromised from pressure. Infections related to fractures and hardware placement are not uncommon in foot reconstruction. These are treated with flap elevation and further debridement.
- Long-term complications include flap ulceration or callus, typically around the flap–native skin interface. In these circumstances, excision of the ulcer with flap advancement is usually sufficient.

CHAPTER The Medial Plantar Flap

Arash Momeni and Subhro K. Sen

DEFINITION

- The medial plantar flap is suitable for reconstruction of heel and lateral plantar defects.^{1,2}
- The medial plantar flap is harvested from the non–weight-bearing instep area of the foot.
- In the majority of cases, the donor site must be skin grafted. Narrow flaps up to 2 cm in width may be closed primarily.
- Volar hand and finger, as well as contralateral foot defects, may be reconstructed with the free medial plantar flap, as it is an excellent source of glabrous skin.^{3,4}

ANATOMY

- The medial plantar flap is centered on an axis extending from the medial aspect of the first metatarsal head distally to the medial horizontal calcaneal eminence (talar shelf) proximally (**FIG 1**).
- Perfusion to the flap is via perforators from the medial plantar artery and venae comitantes that course between the abductor hallucis and flexor digitorum brevis muscles (**FIG 2**).
- Subcutaneous veins can be incorporated into the flap to augment venous drainage.
- The medial plantar flap may be raised as a sensate flap by including branches of the medial plantar nerve.
- It is critical to avoid including the weight-bearing regions of the foot (plantar forefoot, lateral plantar area, and heel) when harvesting this flap (**FIG 3**).

FIG 1 • Design of medial plantar flap.

FIG 2 • Perfusion to the medial plantar flap is via perforators from the medial plantar artery and venae comitantes that course between the abductor hallucis and flexor digitorum brevis muscles.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Preoperative evaluation of patients with plantar foot wounds includes a detailed history, focused physical examination, as well as assessment of the functional limitations associated with the foot defect.
- History
 - A thorough history of pre-existing medical conditions as well as their severity must be obtained. Important conditions to identify and address preoperatively include peripheral vasculopathy, diabetes mellitus, and smoking.
 - Peripheral vasculopathy must be corrected prior to any attempt at reconstructing an existing ischemia-related soft tissue defect.
 - Diabetes mellitus management needs to be optimized to increase the likelihood of an uneventful recovery.
 - Preoperative smoking cessation is mandatory to decrease the risk of delayed wound healing.
 - A focused history of the foot wound with particular emphasis on etiology, duration, changes in size, previous wound-related complications (eg, infections), and previous attempts at treatment is critically important.
- Physical examination
 - The foot wound is inspected and its location and dimensions documented.
 - The foot is inspected for pre-existing scars that may preclude harvest of the medial plantar flap.
 - A thorough neurovascular exam of the lower extremity is performed.
 - Pulses, that is, dorsalis pedis and posterior tibial artery, are palpated.
 - Doppler examination is used to confirm the presence of the medial plantar artery and identify its course.
 - Absence of perfusion to the foot via the dorsalis pedis artery represents a possible contraindication to utilizing the medial plantar flap, depending on arterial inflow via the peroneal artery.
 - Sensory examination using Semmes-Weinstein monofilaments is performed in the distribution of the tibial as well as deep and superficial peroneal nerves.
 - The foot is evaluated for any acquired or congenital deformities, as these could influence the weight-bearing areas of the foot, thus, affecting flap design.

FIG 3 • Note that the medial plantar flap is designed in a manner to not include the weight-bearing regions of the foot.

IMAGING

- Preoperative imaging is not routinely required prior to harvest of the medial plantar flap.
- Traditional or CT angiography can be obtained to confirm the presence of suitable pedicle vessels for patients with peripheral vasculopathy in whom there is concern for involvement of the pedicle vessels or patients with traumatic defects with the possibility of involvement of the medial plantar artery/posterior tibial artery.
- Handheld pencil Doppler examination is typically sufficient to localize the medial plantar artery as well as intermuscular perforators emanating between the abductor hallucis medially and the flexor digitorum brevis muscle laterally.

SURGICAL MANAGEMENT

- Patients with defects of glabrous skin containing areas are generally considered for reconstruction with the pedicled medial plantar flap based on the principle of “replacing like with like.”
- Typical indications include heel and lateral plantar midfoot defects (**FIGS 4 and 5**).
- It may be transferred as a free flap for reconstruction of the contralateral foot as well as volar hand and finger defects.
- It is critical to examine the foot and identify weight-bearing areas so not to include these regions in the flap. The weight-bearing areas include the plantar

forefoot over the metatarsophalangeal heads, lateral plantar foot, and the heel.

FIG 4 • Heel defect.

Preoperative Planning

- Preoperative radiographs of the affected extremity are obtained to assess the bone underlying the defect. It is critical to establish whether osteomyelitis is present. If osteomyelitis is present, it should be adequately treated with debridement and antibiotics prior to reconstructing any existing soft tissue defect.
- Preoperative magnetic resonance imaging (MRI) may be indicated to preoperatively delineate the extent of osseous and soft tissue involvement.⁵
- Handheld pencil Doppler examination is performed to outline the course of the medial plantar artery.
- The medial plantar flap is centered on an axis extending from the base of the first metatarsal distally to the sustentaculum tali. The sustentaculum corresponds to the medial eminence of the calcaneus.
- It is critical to avoid incorporating weight-bearing skin areas of the foot into the flap.
- The flap can be designed with its proximal skin bridge intact or as an island flap depending on the needs of the defect.⁶

FIG 5 • Lateral plantar midfoot defect.

Positioning

- The patient is typically placed in the supine position with the leg externally rotated and knee flexed (“frog leg”). Prone positioning is likewise possible depending on defect location and surgeon preference.
- A well-padded tourniquet is placed on the thigh to provide for a bloodless operative field, which substantially facilitates identification of key structures during flap dissection.

TECHNIQUES

■ Medial Plantar Flap Harvest

- Landmarks: first metatarsal head, medial calcaneal eminence, midline of the plantar surface of the foot, navicular bone.
- The flap is designed within the boundaries of these landmarks, with particular attention paid not to include any weight-bearing areas of the foot (see **FIGS 1** and **3**).
- The foot wound is debrided until healthy-appearing tissue is encountered.
- The lower extremity is elevated, exsanguinated with an Esmarch bandage, and the tourniquet inflated to 100 mm Hg above the systolic blood pressure value.
- Skin incision is made along the borders of the flap, extending through the plantar aponeurosis.

- Although the authors prefer to include the plantar aponeurosis, inclusion of this structure is not mandatory.
- Distally, the abductor hallucis and flexor digitorum brevis muscles are identified.
- Perforators between these muscles are identified, the abductor hallucis muscle is retracted medially, and the perforators are traced to their origin (**TECH FIG 1**).
- The medial plantar artery is visualized, along with the accompanying medial plantar nerve and venae comitantes.
- The medial plantar artery is distally ligated and divided, followed by a distal-to-proximal flap dissection.
 - It is important to maintain all superficial attachments between the medial plantar artery and the overlying skin to ensure flap vascularity.
- In order to avoid sensory loss of the distal medial plantar foot and toes, the medial plantar nerve is not routinely transected.
 - Instead, a nerve-splitting internal neurolysis technique is employed, in which the nerve fibers entering flap are split from the medial plantar nerve, thus preserving distal sensory innervation as well as providing for a sensate flap.
- Dissection is continued proximally until a sufficient arc of rotation is obtained to allow transposition/rotation into the defect.
 - Occasionally, it may be necessary to divide the lateral plantar artery, the abductor hallucis muscle, and the flexor retinaculum to increase the arc of rotation in pedicled flap transfer or to increase pedicle length in cases of microvascular transfer.
 - Release of the tarsal tunnel may be necessary. It may be necessary to follow the medial plantar artery to its origin from the posterior tibial artery. The posterior tibial vessels can also be used for microsurgical anastomosis in the case of free tissue transfer.

TECH FIG 1 • A. During flap harvest, the perforators between the abductor hallucis and flexor digitorum brevis muscles are identified. **B.** The abductor hallucis muscle is retracted medially, and the perforators are traced to their origin.

■ Donor Site Closure

- The donor site of narrow medial plantar flaps up to 2 cm in width may be closed primarily.
- The majority of donor sites require skin grafting for closure.
 - The exposed abductor hallucis and flexor digitorum brevis muscles are reapproximated to provide for a well-vascularized wound bed, amenable to receipt of a split-thickness skin graft (**TECH FIG 2**).
- A negative pressure wound dressing can be applied over the skin graft as a bolster.

TECH FIG 2 • A. Split-thickness skin graft to donor site. **B.** Split-thickness skin graft to donor site

PEARLS AND PITFALLS

Indications	■ Heel and lateral plantar defects (pedicled flap transfer). ■ Any defect requiring reconstruction with glabrous skin (microvascular-free tissue transfer).
Contraindications	■ Previous surgical intervention or injury that violate the area of medial plantar flap harvest. ■ Peripheral vascular disease with occlusion or stenosis of pedicle vessels of significant microvascular disease. ■ Occlusion of dorsalis pedis artery.
Imaging	■ Handheld pencil Doppler examination outlining the course of the medial plantar artery typically sufficient. ■ Routine use of preoperative imaging is not indicated. ■ In cases of peripheral vascular disease or traumatic defects with the pedicle vessels at risk, traditional or CT angiography is useful.
Flap dissection	■ Avoid incorporating weight-bearing skin areas into the flap. ■ Distal-to-proximal flap dissection. ■ Preserve the medial plantar nerve, ie, employ a nerve-splitting approach. ■ May increase pedicle length/arc of rotation by dividing the lateral plantar artery, abductor hallucis muscle, and flexor retinaculum, and dissect the pedicle to the posterior tibial artery.
Donor site closure	■ Up to 2 cm width can be closed primarily. ■ Typically donor site closure requires the use of a skin graft.

POSTOPERATIVE CARE

- The patient is instructed to keep the donor leg elevated for 2 weeks.
- The bolster dressing on the donor site skin graft is typically removed on

postoperative day 5, and routine skin graft care is initiated.

- In cases of soft tissue reconstruction only without any underlying fractures, patients are allowed to ambulate once the flap suture lines and donor site skin graft have healed and are stable. In cases on underlying fractures, weight-bearing status will be determined by orthopedic surgery.
- Meticulous foot care, particularly in patients with diabetes mellitus, is paramount.
- Referrals should be made to an experienced podiatrist for evaluation and possible alterations of foot wear to decrease the likelihood of wound recurrence.

OUTCOMES

- **FIGS 6 to 8** demonstrate representative cases of long-term postoperative outcomes following plantar reconstruction using the medial plantar flap (**FIGS 6 to 8**).
- Siddiqi et al. presented their experience in 18 patients who underwent reconstruction of the weight-bearing heel with the medial plantar artery flap.²
 - Indications for reconstruction included trauma, pressure sores, and unstable plantar scars.
 - No flap loss was reported. Merely one case of partial skin graft loss that healed by secondary intention was observed.
 - Patients were able to wear normal footwear.
 - No functional donor site morbidity was reported.
- Schwarz and Negrini reported on 51 medial plantar artery flaps that were performed in 48 patients.⁷
 - Indications included defects of the posterior heel ($N = 25$), lateral border of the foot ($N = 12$), anterior heel ($N = 10$), and an over the Achilles tendon ($N = 4$).
 - Complications were encountered in 25.5% of the procedures (13/51), with the most common complications being delayed wound healing ($N = 6$) and infection ($N = 3$).
 - One flap loss was reported in addition to 9 ulcer recurrences in 7 ft.

FIG 6 • Long-term outcome after heel reconstruction with the medial plantar flap.

FIG 7 • Long-term outcome after heel reconstruction with the medial plantar flap.

COMPLICATIONS

- Postoperative complications requiring surgical intervention are uncommon.
- Complications, however, can include the following:
 - Infection
 - Wound dehiscence
 - Delayed wound healing
 - Skin graft loss
 - Flap loss
 - Injury to the medial plantar nerve with consecutive altered sensation of the medial forefoot and toes

- Gait disturbance
- Pain
- Unstable scar

FIG 8 • Long-term outcome after reconstruction of a lateral plantar midfoot defect with the medial plantar flap.

14 Reconstruction of Heel and Plantar Defects: Free Flap

CHAPTER

Goo-Hyun Mun and Kyong-Je Woo

DEFINITION

- Heel and plantar soft tissues perform a special role of weight bearing while walking or standing. The heel sustains up to 115% of body weight during slow walking and up to 260% of body weight during running.¹
- Heel and plantar defects may result from several causes such as trauma, diabetes, infection, peripheral vascular disease, frostbite injuries, and tumor resections.
- The goal of reconstruction is aimed at not only providing stable wound healing but also achieving functional restoration of the salvaged limb and maintaining acceptable appearance.

ANATOMY

- The weight-bearing plantar skin is a highly specialized part of the foot that is able to withstand and absorb the forces exerted during gait or running cycles. The epidermis and dermis are much thicker in plantar skin (“glabrous skin”) than in other parts of the body.
- Subcutaneous fat in combination with the vertical fibrous connective tissue provides a cushioning effect to weight bearing.
- The three arteries at the ankle level and their terminating branches in the foot that can be used as recipient vessels for free flaps include the anterior tibial-dorsalis pedis artery, posterior tibial-medial and lateral plantar artery, and peroneal-lateral calcaneal artery.
- Anterior tibial-dorsalis pedis artery: the dorsalis pedis artery passes under the extensor retinaculum at the midpoint between the medial and lateral malleoli. It usually runs across and beneath the extensor hallucis longus (**FIG 1A**). It

passes to the proximal end of the first intermetatarsal space, where it turns into the sole between the heads of the first dorsal interosseous to complete the plantar arch and provides the first plantar metatarsal artery (**FIG 1B**). In heel and plantar reconstruction with a free flap, the dorsalis pedis artery can be reached for the recipient vessel by using a remote incision and subcutaneous tunneling (**FIG 2**). The first plantar metatarsal artery can be used in the plantar forefoot reconstruction (**FIG 3**).

A

B

FIG 1 • A,B. Anterior tibial-dorsalis pedis artery. B.

- Posterior tibial-medial and lateral plantar artery: posterior tibial artery runs midway between the medial malleolus and the medial calcaneal tubercle under the laciniated ligament. It is located between the flexor digitorum longus and flexor hallucis longus tendons (**FIG 4**). The posterior tibial artery divides into the medial and lateral plantar arteries under the origin of the abductor hallucis. While the medial plantar artery runs between the abductor hallucis and flexor digitorum brevis (**FIG 5**), the lateral plantar artery, being usually

larger, travels from medial to lateral position under the proximal third of the flexor digitorum brevis and then continues distally between flexor digitorum brevis and abductor digiti minimi (**FIG 6**).

- Peroneal-lateral calcaneal artery: peroneal artery terminates into lateral calcaneal artery around the lateral malleolus (**FIG 7**). The lateral calcaneal artery was introduced as a pedicle for local flap, but a recent anatomical study suggests that it could be used as a recipient blood vessels for free flap.^{2,3} The lateral calcaneal artery originates either from peroneal artery (80.3%), posterior tibial artery (13.1%), or a common branch from both the peroneal and posterior tibial arteries (6.6%) and runs between lateral malleolus and Achilles tendon.^{3,4}
- The principal superficial veins are termed long (great) and short (small) saphenous veins (**FIG 8**). The long (great) saphenous vein passes anterior to the medial malleolus, whereas the short (small) saphenous vein ascends from the lateral side of the foot. It ascends posterior to the lateral malleolus, passing along the lateral border of the Achilles tendon. A deep venous system runs near the corresponding arteries and develops communication with the great and small saphenous veins. Both deep veins of the corresponding arteries and the superficial veins can be selected as recipient veins in the foot.

FIG 2 • A. The dorsalis pedis artery was used as a recipient artery for defect on lateral forefoot. A remote incision and subcutaneous tunneling was performed to reach the recipient vessels. **B.** Microvascular anastomosis. **C.** Immediate postoperative photo. **D.**

Another case with defect on the lateral heel. Dorsalis pedis vessels were used as recipient vessel through a remote incision and subcutaneous tunneling. **E.** Immediate postoperative photo.

FIG 3 • A,B. First plantar metatarsal artery and vein for the recipient vessel.

FIG 4 • A–C. The posterior tibial artery for the recipient vessel.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough medical history and examinations for sensation and presence of

diabetes, peripheral vascular disease, and existence of osteomyelitis need to be obtained. Deformities of the foot and a postoperative rehabilitation plan should also be considered in the selection of reconstruction methods.

- Vascular anatomy and patency must be evaluated. In this regard, noninvasive Doppler ultrasound exam is a simple and useful evaluation method. Recently, computed tomography (CT) or magnetic resonance (MR) angiography methods are also recommended for vascular imaging.

IMAGING

- The authors routinely perform preoperative CT angiographic examination of the lower extremities, except when contraindicated.
- Bone assessment includes plain radiography and bone scan or MR imaging for the diagnosis of osteomyelitis.

SURGICAL MANAGEMENT

- For large and extensive heel and plantar defects, the free flap transfer procedure is preferred because it can provide a large amount of tissue with various tissue components for obliterating deep and/or extensive wounds. The early and definitive reconstruction of compound defects leads to a dramatic improvement in the rate of lower extremity salvage and restoration of the weight-bearing function and normal gait pattern.

FIG 5 • A–C. The medial plantar artery for the recipient vessel.

- The final choice of most suitable flap depends on the surgeon's preference and the patient's needs. A form of durable, permanent, pain-free, and functionally and aesthetically satisfying coverage should be achieved in the heel and plantar reconstruction.

FIG 6 • A–C. The lateral plantar artery for the recipient vessel.

- Free muscle flap versus fasciocutaneous flap: free muscle flap (rectus abdominis, latissimus dorsi, or gracilis) has been used commonly for extensive foot defects. A muscle flap has advantages, including the large amount of tissue availability, and ability to obliterate dead space especially in defects with irregular contours, where there is greater ease to form three-dimensional (3D) shapes.⁵ In contrast, recent clinical studies have demonstrated that fasciocutaneous flaps (anterolateral thigh, thoracodorsal artery perforator [TDAP] flap) provide a sufficient amount of bulk, large, and pliable skin flap, with acceptable donor site morbidities.^{6,7} The donor site morbidities caused by harvesting the muscle flap and additional donor site for skin graft can be avoided by using the fasciocutaneous flap.

FIG 7 • A–D. The lateral calcaneal artery for the recipient vessel.

FIG 8 • A superficial venous system of the foot.

- The authors prefer the TDAP flap for many foot defects because it provides thick skin from the back that has negligible incidence of atherosclerosis of the vascular pedicle, which is relatively long. Furthermore, the TDAP can be tailored to include different tissue types such as muscle (latissimus dorsi) and/or bone (scapula) depending upon the requirements for reconstruction. The anterolateral thigh flap is also useful when supine position of the patient is favorable.
- Muscle-chimeric perforator flap is useful to obliterate dead space when it is necessary (see **FIG 12B,C**).

- Innervated (sensate) flap: although it seems reasonable to assume that plantar reconstruction requires a sensate flap to avoid recurrent ulceration, there is no evidence suggesting that innervated flaps on weight-bearing portion of the foot is superior in terms of rates of ulceration. A noninnervated fasciocutaneous flap showed progressive improvement in sensitive thresholds, achieving good protective sensitivity, similar to that of an innervated flap.⁹
- The status of an underlying skeletal anatomy is a critical factor in the durability of the soft tissue reconstruction. Abnormally high pressure points on the plantar surface lead to the recurrent breakdown after reconstruction, and the abnormalities should, therefore, be corrected.
- In the heel and plantar reconstructions, restoration of 3D configuration of the heel and plantar foot is essential to wear a normal shoe and to regain normal gait pattern. The primary defatting and wedge resection of the flap facilitates making 3D configuration.

FIG 9 • A clinical case with malignant melanoma on the left heel.

Preoperative Planning

- The patient had a large malignant melanoma on the left heel. Wide excision of the tumor and reconstruction of the heel were planned (**FIG 9**).
- CT angiographic evaluation showed all major vessels of the foot had normal anatomy with no atherosclerosis or vascular occlusion. The presence of a sizable lateral calcaneal artery on the patient's left foot was also confirmed, and the course could be followed by 3D reconstruction of the CT images (**FIG 10**).
- A TDAP flap, instead of an anterolateral thigh flap, was planned to be used for

several reasons in the described case. Lateral position was better than supine position for both tumor resection and inset of the flap. In addition, it might have been necessary to perform a skin graft for the anterolateral thigh flap donor site if the flap was more than 10 cm wide.

FIG 10 • A,B. CT angiographic image of lateral calcaneal artery.

Positioning

- The procedure can be performed in the lateral decubitus position, with the affected leg placed on the upper side. An ipsilateral TDAP flap can be harvested following tumor resection, without changing the position, at the same time as dissecting the lateral calcaneal artery as the recipient artery.
- When the posterior tibial artery is planned to be the recipient vessel, a TDAP flap is harvested from the contralateral side in a position of lateral decubitus with the recipient foot placed on lower side (**FIG 11**).

FIG 11 • Lateral decubitus position for harvesting TDAP flap on the contralateral side of the defect when the posterior tibial artery is used as recipient vessel.

Approach

- When a recipient vessel can be found in the defect, it is approached directly. Otherwise, an extended incision starting from the defect or a separate incision with subcutaneous tunneling is used as an approach to preparing the recipient vessels.

TECHNIQUES

Video p7-c014

Note: Each step of techniques is included in the video clip.

■ Wound Preparation

- It is critical that there is complete debridement or excision of pathologic, necrotic, or infected tissue under tourniquet control (**TECH FIG 1**).

TECH FIG 1 • A,B. Defect of the heel after tumor resection.

■ Recipient Vessel Preparation

- Patency and location of the lateral calcaneal artery for use as the recipient artery are checked using handheld pencil Doppler.
- Small saphenous vein is preserved and dissected for use as the recipient vein.
- The lateral calcaneal artery runs superficially between lateral malleolus and the Achilles tendon. The vessel traverses anterior to the calcaneal tendon and posterior to the small saphenous vein (**TECH FIG 2**). Opening the extensor retinaculum and deep fascia exposes the lateral calcaneal artery with its associated venae comitantes.

TECH FIG 2 • Dissection of lateral calcaneal vessels.

■ Assessment of the Defect

- After deflating the tourniquet, meticulous hemostasis is performed, which is followed by irrigation with saline.
- A template of the exact shape and size of the defect is made by using a transparent plastic or paper to be used when designing the flap.
- Wedge-shaped excision of the skin flap is necessary in case of the total heel resurfacing. The area for planned wedge excision is incorporated when estimating the flap dimensions.

■ Flap Harvest

- Outline of the relevant muscle and landmarks are marked on the skin.
- Perforators are located using handheld pencil Doppler, and the flap is designed using a template of the defect. The perforator can be located eccentrically, considering the area of wedge excision (**TECH FIG 3A**).
- A limited incision is made, and a suprafascial dissection is performed until the targeted perforator is identified. Once the perforator is evaluated and deemed suitable, then the whole skin paddle is elevated and meticulous intramuscular dissection of pedicle with bipolar forceps is commenced.
- Motor nerve branches to the muscle are preserved, and the pedicle is divided when sufficient length is obtained (**TECH FIG 3B**).
- A closed suction drain is placed, and the donor site is primarily closed in layers (**TECH FIG 3C**).

TECH FIG 3 • A–C. Flap design and elevation.

■ Microanastomosis with Temporary Inset

- Temporary inset of flap can be performed using a skin stapler.
- It is critically important to avoid twisting of the pedicle. If excessively long, the vascular pedicle under the flap is positioned in lazy-S shape to avoid kinking.
- The pedicle artery is anastomosed to the lateral calcaneal artery, and the vein is anastomosed to the short (small) saphenous vein (**TECH FIG 4**).
- Vascular clamps are removed after completion of the anastomosis. Warm saline is applied onto the vessels and flap, and inflow and outflow of the flap are checked after waiting for several minutes.
- A thorough microscopic evaluation is conducted to find any bleeding points along the vascular pedicle.

TECH FIG 4 • Microanastomosis.

■ Final Inset

- Defatting of the flap is performed before the final inset. The deep fat and part of the superficial fat may be carefully removed with scissors according to the required thickness of tissue. Thinning can be done with or without loupe, but microscope magnification is not usually necessary. This procedure is important to obtain an optimal contour of the reconstructed foot. The authors prefer primary (immediate) defatting to secondary (delayed) defatting because it provides well-contoured reconstruction in one stage, reduces tension of closure, and is a safe procedure. Alternatively, secondary defatting is a viable option, which can avoid potential risk of circulatory problem associated with primary thinning.
- In contrast to the conventional fasciocutaneous flap that includes deep fat and fascia, a perforator flap with a thin subcutaneous layer composed of the superficial fat lobules surrounded by dense fibers allows the skin to anchor tightly to the surface and to glide less.^{6,7} Generally, perforator flap is thinned accordingly to match the contour of adjacent plantar tissue.
- Redraping of the flap for the final inset is attempted only after the defatting procedure is completed because this may change the pliability and extensibility of the flap. Dimensional excess should be corrected at this stage by careful trimming to obtain durable weight-bearing surface against anticipated shear forces (**TECH FIG 5**).
- The wound is closed over a drain placed under the flap to prevent fluid collections.

- Fluffed gauze is gently applied to the flap, but the part of flap including the location of captured perforator is left exposed for postoperative monitoring using the handheld pencil Doppler.

TECH FIG 5 • A,B. Inset of the flap after defatting and wedge-shaped excision.

PEARLS AND PITFALLS

Reconstruction goal

- The weight-bearing plantar skin is highly specialized to withstand and absorb forces exerted during gait or running cycles.
- The reconstructive goal is not only to provide stable wound healing but also to achieve functional restoration of the salvaged limb with an acceptable appearance.

Flap selection

- Free muscle flaps (rectus abdominis, latissimus dorsi, and gracilis) have been commonly selected for the extensive foot defects.
- Cutaneous perforator flaps now provide favorable functional and aesthetic outcomes in heel and plantar reconstruction.

Selection of recipient vessel

- The three named arteries at the ankle level and their terminating branches can be candidates for recipient vessels; anterior tibial-dorsalis pedis artery, posterior tibial-medial and lateral plantar artery, and peroneal-lateral calcaneal artery.
- CT angiography is a valuable tool to evaluate the arterial and venous flows and the presence of atherosclerosis.

Assessment of the defect

- Before designing the flap, the size and shape of the defect are measured exactly by making a template.
- Required vascular pedicle length and flap thickness are also assessed.

Flap inset

- Defatting of the flap at the time of inset is important to obtain a desirable contour of the reconstructed foot. Alternatively, secondary defatting is an option.
- Excessive skin dimension is carefully corrected to have the flap closely tailored to the defect.

POSTOPERATIVE CARE

- The leg is elevated to help with edema for a better venous return while the patient is lying in bed.
- Care should be taken to avoid any compression along the course of the superficial vein of the leg when it is used as an outflow vessel.
- There is no consensus regarding the use of medications for thromboprophylaxis such as aspirin, heparin, and dextran. The authors do not routinely use any of these medications but low molecular weight heparin is given for chemoprophylaxis of the venous thromboembolism while patient is immobilized in bed.
- For postoperative monitoring, the flap can be checked every 1 to 3 hours for the first 48 hours, followed by every 4 to 6 hours for the next 48 hours after the surgery. Monitoring is done by physical examination and handheld pencil Doppler examination.
- Diet is usually allowed 24 hours after surgery in the authors' practice.
- Although the duration of immobilization time varies based on the orthopedic and bony status, in general, progressive weight bearing and ambulation are achieved once the flap maturation is assured. At 2 weeks, compressive garment is applied to prevent edema of the flap and foot. Bearing weight on the site of flap is usually allowed in 4 weeks after the surgery.
- Abnormal weight-bearing patterns and gait abnormalities correlate with the development of chronic ulcers. An early orthotic use and physical therapy in rehabilitation unit may prevent ulceration and wound breakdown.
- Patient education on meticulous foot care with frequent inspections to recognize any area of wound breakdown is essential for a successful and durable result.

FIG 12 • A. Total heel reconstruction using TDAP flap. Posterior tibial vessels were the recipient vessels. **B,C.** Reconstruction for small heel defect with muscle-chimeric TDAP flap. Anterior tibial vessels are the recipient vessel. **D.** Reconstruction of the plantar midfoot with TDAP flap, using lateral plantar vessels as a recipient vessel. **E.** Reconstruction of lateral forefoot with TDAP flap, using posterior tibial vessels as a recipient vessel through subcutaneous tunneling. **F.** Reconstruction of medial forefoot with TDAP flap, using the first plantar metatarsal vessels as a recipient vessel.

OUTCOMES

- Microvascular free flap for foot reconstruction is, at present, a safe and reliable procedure, with high success rate.¹⁰ Recently, the plantar reconstruction using the perforator flaps showed a success rate of between 97.5% and 98.5%, with acceptable functional and aesthetic outcomes.^{5,6}
- Microvascular free flap is a reliable reconstructive option for a variety of size defects on various locations of the heel and plantar foot (**FIG 12A**). Multiple tissue components such as cutaneous and chimeric muscle (**FIG 12 B,C**) can be used according to tissue requirements.

COMPLICATIONS

- Vascular complications such as venous and arterial thrombosis.
- Hematoma: early diagnosis of a hematoma under the flap is critical for its evacuation to prevent the obstruction of anastomotic site from the expanding hematoma.
- Infection.
- Ulcerations: ulceration is one of the most common complications of free flap reconstruction of the heel. Although flap-specific factors may contribute to its development, it is possible that flap extrinsic factors such as the recipient bed, bony prominence, Contouring of the flap, and footwear may be more important.

The Reverse Sural Artery Flap for Lower Extremity Reconstruction

15 CHAPTER

Ashkaun Shaterian and Amber Leis

DEFINITION

- The reverse sural artery flap was first described by Donski and Fogdestam¹ and later by Masquelet et al.² and represents a fasciocutaneous flap used in lower extremity reconstruction.
- As a one-stage or two-stage operation that does not require microsurgical techniques, the reverse sural flap is an option available to most reconstructive and orthopedic surgeons.

ANATOMY

- The blood supply for the skin paddle of the distal two-thirds of the leg depends on the sural arteries along its most proximal course and the peroneal artery perforators more distally.
- The reverse sural artery flap receives retrograde arterial flow through septocutaneous perforators that originate from the peroneal artery and directly anastomose with the superficial sural artery.
- There are typically two to five perforators located 5 to 7 cm proximal to the lateral malleolus.³
- The venous drainage for this flap is composed of a venous network of the superficial sural vein, the lesser saphenous vein, and the associated veins of the peroneal artery.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Assessment of the defect begins with evaluation for missing tissues, exposed vital structures, and presence of underlying orthopedic hardware.

- If healthy subcutaneous or granulation tissue presides, the wound may be amenable to skin grafting.
- If exposure of tendon, artery, vessel, or bone are present, more definitive coverage with fasciocutaneous or muscle flaps is often necessary.
- The size of the defect will also influence the reconstructive choice.
- The reverse sural artery flap can be used to cover defects of the posterior aspect of heel and Achilles tendon, anterior and lateral ankle, dorsum of the foot, lateral aspect of the hindfoot, and the anterior crest of lower third of the leg.
- Physical exam to evaluate the vascular status of the extremity, and to evaluate for peripheral artery disease or venous insufficiency, is necessary as they may influence flap survival.
- Patient comorbidities of diabetes mellitus, lower extremity venous insufficiency, and peripheral artery disease have been associated with flap necrosis and represent relative contraindications.
- The presence of an occluded anterior or posterior tibial artery does not represent an absolute contraindication to this flap; however, most consider occlusion of the peroneal artery to preclude its use.⁴⁻⁶

IMAGING

- Rarely are radiographs necessary except in the evaluation of bone abnormalities.
- Preoperative angiograms are not routinely obtained but may be useful in patients with pertinent exam findings or in traumatic wounds of the lower extremity.

SURGICAL MANAGEMENT

Preoperative Planning

- The reverse sural artery flap is a fasciocutaneous flap that can be designed with either a complete skin bridge overlying the pedicle or as an island skin flap with an adipofascial pedicle.
- Preoperatively, the peroneal perforators and lesser saphenous vein are identified with Doppler ultrasonography.
- The lesser saphenous vein is used to determine the oblique axis of the pedicle and the flap.
- The flap is designed on the posterior aspect of the calf between the two heads

of gastrocnemius at the junction of upper and middle third of the leg (**FIG 1**).

- The dimensions of the flap are determined by the arc of rotation and the size of the defect; however, a reliable flap should not exceed a ratio of length to width of pedicle of 4:1.
- The flap dimensions can reach 15 cm in length and 12 cm in width, but when the flap is less than 3 to 4 cm wide, the donor site defect can be closed primarily.
- The pivot point of the pedicle is dependent on the main perforator and is located 5 cm or three fingerbreadths proximal to the tip of the lateral malleolus and posterior to the fibula.
- The flap may also be designed based on more distal perforators, but the dissection becomes more risky, the width of pedicle decreases, and reliability of the flap declines.

FIG 1 • Flap markings for a reverse sural artery flap with a fasciocutaneous pedicle.

Positioning

- To provide the best exposure, the patient is placed in a prone or lateral position depending on the location of the defect.
- In the lateral position, flexion and adduction of hip and flexion of knee allow for easier access.
- The surgeon is positioned on the same side as the flap and the assistant on the contralateral side.
- All bony prominences should be well padded and the upper extremities and neck placed in positions of safety.

Approach

- The flap is approached from the posterior lower leg after identifying the vascular pedicle and completing the appropriate markings.

TECHNIQUES

■ Reverse Sural Artery Flap

- A well-padded lower extremity tourniquet is applied.
- The skin incision begins along the location of the pedicle and continues around the proximal edge of the flap (**TECH FIG 1A**).
- The subcutaneous tissue is dissected along the pedicle and most proximally to identify and expose the sural nerve, superficial sural artery, sural vein, and lesser saphenous vein.
- At the proximal margin of the flap, the nerve and the vessels are ligated and divided.
- The flap including the skin and subcutaneous tissues containing the neurovascular structures are elevated off the surface of the gastrocnemius muscle in a subfascial plane to the level of the chosen pivot point (**TECH FIG 1B,C**).
- These tissue layers are elevated as a single fasciocutaneous unit and continue distally to isolate the pedicle.
- The pedicle should be at least 2 to 3 cm in width after its dissection from the surrounding tissues.
- The pedicle is dissected free at the pivot point, mobilized, and the flap repositioned to cover the recipient site. It is important that the arc of rotation does not kink or place undue tension on the pedicle.
- Transposition of the flap through either a wide subcutaneous tunnel or an excised skin bridge allows for flap inset.
- The donor site is closed primarily or covered with a split-thickness skin graft.
- At the completion of the case, dressings are applied. The skin graft (if needed) is covered with nonadherent dressings and antibiotic ointment. Nonadherent gauze is used to cover suture lines.
- A well-padded posterior plaster splint with a window for flap monitoring is

applied to cover and protect the surgical site.

TECH FIG 1 • A. Flap dissection with the fasciocutaneous pedicle incised. **B.** Flap after inset (as a second stage following a delay procedure) with split-thickness skin grafting to the donor site. **C.** Reverse sural artery flap after flap dissection and elevation.

■ Delayed Reverse Sural Artery Flap

- The delayed reverse sural artery flap aims to improve longitudinal blood flow along the axial pedicle and decrease flap necrosis and is especially useful in patients with vascular comorbidities.
- The described techniques have included raising the flap in the typical subfascial plane but without incising the proximal portion of the skin island

flap.

- The skin is closed and 1 to 2 weeks later completely elevated and transposed.
- Others have described complete elevation of the flap at the first stage following flap transfer at the second stage.
- These staged techniques establish improved flap circulation prior to the trauma of flap transfer.

■ Supercharged Reverse Sural Artery Flap

- The supercharged reverse sural artery flap aims to improve venous drainage and bypass venous valves that prevent retrograde venous outflow.
- Described techniques include anastomosing the proximal segment of the less saphenous vein to a vein located at the recipient site or exteriorizing the proximal segment to allow for intermittent drainage upon signs of vascular congestion.⁴

PEARLS AND PITFALLS

Imaging

- Consider imaging to evaluate the patency of the peroneal artery in traumatic wounds of the lower extremity.

Technique

- A longer pedicle will allow for tension-free twisting; excessive pedicle rotation at the pivot point can result in a kinked pedicle and flap failure.
- It is preferable to incise the skin bridge between the pivot point and recipient site to prevent retractile tissue from compressing the pedicle.
- The pivot point of the flap can be revised at a later operation (ie, delayed flaps).
- The use of a skin pedicle (vs adipofascial) improves venous return but limits rotation of the flap.
- A pedicle width of at least 4 cm has been recently shown to improve venous drainage and flap viability.³
- The reverse sural flap is often at risk for venous congestion where impaired venous drainage is thought to be a major contributor to flap failure. Widening the pedicle, performing a delayed flap, or

supercharging the flap may overcome this problem.

POSTOPERATIVE CARE

- In the immediate postoperative period, direct pressure on the flap must be avoided and strict elevation of the lower extremity is instructed.
- The splint and dressings are removed at 5 to 7 days to allow for complete evaluation of the flap and assessment of skin graft viability.
- Prolonged use of a splint beyond the first week is discouraged but may be continued based on the underlying orthopedic status of the bone.
- Nonadherent dressings are reapplied and maintained for 2 to 3 weeks.
- The patient is maintained nonweight bearing for 1 to 2 weeks and restricted weight bearing for 4 to 6 weeks until flap viability and healing is established.

OUTCOMES

- The reverse sural artery flap has a low complication profile with 82% of flaps healing without any flap-related complications on meta-analysis.⁴
- Morbidity associated with selection of this flap includes loss of sensation over the donor site and lateral foot, presence of a donor site scar, and excess foot bulk that may preclude proper footwear.

COMPLICATIONS

- Rate of specific complications range in the literature and include partial or complete flap necrosis, venous congestion, infection, hematoma, delayed healing, wound dehiscence, and skin graft loss.
- Patients with vascular comorbidities (ie, diabetes, venous insufficiency, peripheral artery disease), for example, have a five- to sixfold increase in complication rate relative to their healthier counterparts.⁷
- Age over 40 has also been shown to correlate with flap failure.^{4,7}

16 Ankle Reconstruction With Free Flap

CHAPTER

Sean S. Li, Ahmed Suliman, and Deepak M. Gupta

DEFINITION

- The ankle has limited soft tissue for protection of vital structures, and trauma or tumor extirpation often leads to exposed tendons, bone, vessels, or nerves.
- There are few reliable local flaps that can be used for coverage in this area.
- Impaired blood flow is also typical of the distal lower extremity especially in high-risk patients with comorbidities such as smoking, diabetes, peripheral arterial disease, and venous insufficiency, which may result in ulceration, infection, and necrosis of the soft tissues ultimately requiring free flap coverage.
- Due to the complexity of the ankle, reconstruction ideally should be approached in a multidisciplinary fashion consisting primarily of collaboration between plastic and orthopedic surgeons but also with consideration of consultation of infectious disease and vascular surgery.

ANATOMY

- The ankle is a hinge joint with articulations between the tibia, fibula, and talus.
- Defects in the ankle commonly expose bone or orthopedic hardware, usually at the tibia or the medial and lateral malleoli.
- Five nerves supply the foot and ankle—saphenous, sural, deep peroneal, superficial peroneal, and tibial nerves.
- Knowledge of the ankle's vascular anatomy is essential for limb salvage. The distal lower extremity's arterial supply is primarily supplied by three vessels: posterior tibial (PT), anterior tibial (AT), and peroneal.
- The AT artery branches from the popliteal artery, and its course across the ankle is shown (**FIG 1**, left).

- The PT and peroneal arteries originate from the tibioperoneal trunk, and their courses across the ankle are shown (**FIG 1**, right).

PATHOGENESIS

- Defects of the ankle requiring free flap reconstruction originate from trauma (**FIG 2**), tumor extirpation, and peripheral vascular disease.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Evaluation of the patient begins with history and physical focusing on the following:
 - Eliciting the etiology of the wound and presence of comorbidities including smoking, diabetes, obesity, and peripheral vascular disease
 - Assessing the overall function of the patient and considering the potential outcomes for the patient and bearing in mind the patient's rehabilitative potential, motivation, and compliance. Location, size, depth, character of the wound, and exposed structures
 - Neurological, vascular, and skeletal evaluation of the lower extremities utilizing physical exam, imaging, and Doppler

IMAGING

- Plain films of the defect should be obtained to evaluate for fractures and bony defects with further computed tomography imaging to be considered depending on complexity of the injury.
- If physical or Doppler exam reveals inconclusive vascular status or if peripheral vascular disease is suspected, preoperative arteriography may be obtained.
- Computed tomographic angiography (CTA) (**FIG 3**) can obtain vascular information valuable for flap planning and assessing the recipient site without risk of complications associated with arterial puncture of the groin.
- Selective preoperative CTA may be considered in patients who have lost peripheral pulses, had a neurological deficit secondary to the injury, or of a compound fracture that has undergone reduction and external or internal fixation.²

NON OPERATIVE MANAGEMENT

- Defects in the ankle that typically require free flap reconstruction have exposed hardware, tendon devoid of paratenon, vessels, nerves, open joint(s), or bone denuded of periosteum.

- These defects if managed nonoperatively will not heal and can potentially lead to further tissue loss, osteomyelitis, loss of function, or amputation.

SURGICAL MANAGEMENT

- The goal of reconstruction is to achieve a healed wound to allow function.
- In the ankle, the aims are to allow the patient to wear normal footwear, avoid bulky flaps, and return to weight bearing and ankle motion.
- Selection of flaps is based on morbidity of the donor site and accessibility of local tissue.
- Regardless of the flap selection, the principles for reconstruction include adequate debridement, restoring skeletal support, and anastomosing of the flap vessels outside of the zone of injury.³

FIG 1 • *Left:* the anterior tibial artery course across the ankle.¹ *Right:* the posterior tibial artery and peroneal artery course across the ankle.¹

FIG 2 • A. Exposed bone of medial malleolus, denuded of the periosteum, chronic inflammation, and scarring of surrounding soft tissues. **B.** Necrotic bone within medial malleolus wound.

FIG 3 • CTA shows normal angiogram of bilateral thighs and three vessel runoff of the legs.

- After the evaluation of the patient as a whole in regard to their systemic conditions, socioeconomic factors, extent of injury, and rehabilitative potential, a decision for amputation versus salvage can be made.
- The decision for free flap reconstruction goes hand-in-hand with the patient's orthopedic injuries and potential for functional recovery.
- Scores such as the Mangled Extremity Severity Score (MESS), Predictive Salvage Index, and the Limb Salvage Index can be used to assist in the decision-making for amputation versus salvage.⁴
- Absolute indications for amputation include complete disruption of the

posterior tibial nerve in adults and crush injuries with warm ischemia time greater than 6 hours.

- Relative indications of amputation include serious associated polytrauma, severe ipsilateral foot trauma, and prolonged anticipated course to soft tissue coverage and tibial reconstruction.

Preoperative Planning

- If reconstruction is indicated, the following must be considered:
 - Bony stability is first established by utilizing external or internal fixation devices.
 - External devices are usually preferred if there is significant bone loss or bone devascularization.
 - In contaminated wounds, multiple stages of debridement may be required until an adequate wound bed without devitalized or infected tissues is achieved.
 - Vacuum-assisted closure decreases need for dressing changes and can promote healing.⁵
 - Osteomyelitis can follow severe open fractures with massive contamination or devascularized tissue; management includes resection of dead or infected bone, flap coverage with obliteration of dead space, and antibiotic treatment.⁶
 - Timing of reconstruction
 - If the general condition of the patient and the status of the wound are adequate, definitive coverage should not be delayed.
 - Ideally, the wound should be covered in the first week after injury in the acute phase as further delay causes the wound to enter into the subacute and chronic phases when there is a higher rate of infectious complications and flap failure.^{7,8}
 - Zone of injury⁹
 - Many lower extremity wounds result from high-energy trauma that creates a significant “zone of injury.”
 - This zone is highly thrombogenic and extends beyond what is macroscopically evident.
 - Failure to recognize the true extent of the zone is a leading cause of microsurgical anastomotic failure.
 - Within this zone, there is increased friability of the vessels and increased

perivascular scar tissue.

- Selecting a recipient vessel outside of this zone of injury with good vessel wall pliability and high-quality blood flow from the transected end of the vessel is essential for successful microsurgical anastomosis.

■ Coverage after tumor extirpation

- Free flap reconstruction must withstand radiation therapy and/or chemotherapy with the goal of preserving function and achieving an acceptable appearance and function.
- Close cooperation with oncologists and knowledge of prognosis/risk of recurrence/survival, tumor characteristics, behavior, and adjuvant treatment is necessary to plan for the correct type of reconstructive procedure.

■ Exposed hardware

- Traditionally management involved irrigation and debridement, antibiotics, and removal of hardware.
- However, if the hardware is clinically stable, exposure is less than 2 weeks, the infection is controlled, and the hardware is utilized for bony consolidation, then the likelihood of salvage with soft tissue coverage is increased.¹⁰

■ Reconstruction in patients with a two- or one-vessel extremity

- Consider vascular bypass surgery.
- End-to-side anastomosis during free flap reconstruction can preserve the existing main arteries.
- A flow-through free flap can be utilized where an anastomosis is made both proximally and distally to vessels in the leg (**FIG 4**).
- Some have reported that an anastomosis can technically also be made to a distal stump of a recipient vessel to rely on arterial backflow¹¹; however, this should be a last resort and consideration should be made for possible low flow state.

■ Muscle versus fasciocutaneous free flaps

- Controversy exists over selecting the type of flap for lower extremity defects.

FIG 4 • The flap has been anastomosed end-to-end to the posterior tibial artery. After flowing through, another end-to-end anastomosis allows circulation to the foot through the posterior tibial artery via the rectus femoris branch.

- Reconstruction of wounds with muscle flaps has been shown experimentally to have increased blood flow and antibiotic delivery, increased oxygen tension, increased phagocytic activity, and decreased bacterial counts when compared to fasciocutaneous flaps.¹²
- Arguably muscle flaps are technically less challenging, can fill larger defects, and can be harvested with decreased operative time compared with fasciocutaneous flaps (eg, vastus lateralis flap versus anterolateral thigh flap).¹³
- Donor site morbidity of muscle flaps can be greater than fasciocutaneous flaps depending on the muscle selected.
- Selection of a flap depends on the defect, condition of the wound, goals of reconstruction, and surgeon and patient preference.

Positioning

- Patient positioning in free flap surgery is an important issue that needs to be considered preoperatively. Most cases can be done in supine, supine frog leg, or lateral decubitus position.
- The goal is to avoid unnecessary repositioning of the patient intraoperatively in order to save anesthetic and operative time.
- The location of the defect or choice of recipient vessels may determine the

positioning of the patient and to some extent, the flap choice.

- For example, anterior defects favor the use of the anterolateral thigh flap, gracilis flap, rectus abdominis flap, etc.
- Posterior tibial recipient vessels (medial leg approach) may favor either supine or lateral decubitus position and the concordant flap choices.

Approach

- The approach to flap harvest depends on the flap selection and considering the positioning of the patient as noted above.
- The approach to the ankle wound depends on the location of the defect and selection of recipient vessels.
- The posterior tibial artery is the most commonly used recipient vessel.
 - It is easily accessible by a medial approach and is found between the deep posterior and superficial posterior compartments. In other terms, it is deep to the soleus muscle.
 - The most favorable positioning for the patient is either lateral or with frog leg positioning.
 - It is the preferred vessel for defects of the posterior or medial ankle.
 - It may also be used for lateral defects, and there are several options for pedicle routing, such as under the Achilles tendon.
- The anterior tibial artery is the second most commonly used recipient vessel.
 - It is easily accessible in the anterior compartment.
 - The most favorable positioning of the patient is supine.
 - Some may favor the anterior tibial vessels for defects of the anterior and lateral ankle.
- The peroneal artery is usually the last choice for recipient vessel because of difficulty of accessibility, which may require removal of fibular bone.
- The two major superficial veins of the lower extremity are the great and small saphenous veins, which run superficial to the fascia cruris.
 - The great saphenous vein is accompanied by the saphenous nerve and is located anterior to the medial malleolus.
 - The small saphenous vein arises from the lateral side of the foot, posterior to the lateral malleolus, and passes along the border of the Achilles tendon.
 - Any superficial vein with adequate caliber can be used as a recipient vein in addition to the venae comitantes of the major arteries.
 - Anastomosis of two recipient veins for each artery is optional. If undertaken,

it is preferable to anastomose to separate drainage systems (eg, one deep vein and one superficial vein).

TECHNIQUES

■ Vastus Lateralis

- Take into account all of the preoperative factors as noted in the preoperative planning section.
- Assess the defect.
- Approach your recipient vessel as mentioned in the various approaches above, and dissect back to healthy vessel outside of the zone of injury (**TECH FIG 1A**). Use of tourniquet may be considered.
- Elevate the flap as previously described.¹³
 - With the patient positioned supine, a line is drawn between the anterior superior iliac spine and the superolateral corner of the patella on the donor thigh.
 - An incision is then made along the middle third of the line. Carry the incision through the muscle fascia until the interval between the rectus femoris and the vastus lateralis is identified. Extend the incision as needed as you go along. Take care to identify any branches of the lateral cutaneous femoral nerve so as not to injure them.
 - Separate the rectus femoris and vastus lateralis and identify and preserve the pedicle (the descending branch of the lateral circumflex femoral artery), which is generally visible along the medial border of the vastus lateralis.
 - Perform a lateral subfascial dissection superficial to the muscle until the width of muscle flap needed has been visualized. Continue this dissection proximal and distal along the superficial surface of the muscle until the dimensions of muscle flap needed have been achieved.
 - Identify the motor nerve branches, which typically enter the midportion of the muscle; only sacrifice branches directly involved in the transferred portion of muscle.
 - Dissect the pedicle from distal to proximal. Continue the dissection until adequate pedicle length and vessel caliber has been obtained. One may encounter vascular branches to the vastus intermedius or rectus femoris,

which can typically be sacrificed. Nerve branches should be spared.

- Divide the muscle along the required dimensions. Ligate and divide the pedicle when the recipient area is ready.
- Perform your anastomosis (**TECH FIG 1B**) and inset the flap (**TECH FIG 1C**). Consider use of penrose drains around the microvascular anastomoses. Some additional de-epithelialization or resection of leg skin may be required to accommodate flap and/or pedicle lie.
- Harvest split-thickness skin graft for the flap. Meshing of the skin graft may be considered (**TECH FIG 1D**).
- The donor site can usually be closed primarily over closed suction drains.

TECH FIG 1 • A. The posterior tibial artery and two venae comitantes have been dissected proximal to the zone of injury. **B.** The descending branch of the lateral circumflex femoral artery has been dissected (*blue loop*) to its origin along with the rectus femoris branch (*red loop*). **C.** The flap has been anastomosed in flow through configuration outside the zone of injury. The inset is partially completed with Vicryl sutures. Intervening leg skin was subsequently de-epithelialized to accommodate flap and pedicle lie. **D.** The flap has been inset and covered with a meshed

split-thickness skin graft.

■ Anterolateral Thigh (ALT)

- Take into account all of the preoperative factors as noted in the preoperative planning section.
- Assess the defect.
- Approach your recipient vessel as mentioned in the various approaches above, and dissect back to healthy vessel outside of the zone of injury. Use of tourniquet may be considered.
- Elevate the flap as previously described.¹⁴
 - With the patient positioned supine, a line is drawn between the anterior superior iliac spine and the superolateral corner of the patella on the donor thigh.
 - Draw a 3-cm circle centered at the midpoint of this line. Map the cutaneous perforators with a portable, handheld pencil Doppler probe. The majority of perforators will be found in the inferolateral quadrant of this circle.
 - The flap is centered over the location of these vessels, and its long axis should be parallel to that of the thigh. The maximum width of the flap is judged with a pinch test.
 - Incise the medial border of the proposed flap and continue dissection deep and through the muscle fascia until you have identified fibers of rectus femoris.
 - Continue the subfascial dissection from medial to lateral. Take care to identify the interval between vastus lateralis and rectus femoris and not cross it. At this point, the dissection should be slowed so that one can identify and preserve any septocutaneous or musculocutaneous perforators corresponding to the cutaneous Doppler signals.
 - Once the dominant perforator(s) have been identified, these are carefully dissected distal to proximal, to either free them from the vastus lateralis muscle or include them with a cuff of muscle.
 - Incise the skin paddle along its lateral aspect. Perform a subfascial dissection to the dissected perforators.
 - Depending on the vascular configuration, vastus lateralis muscle can also be dissected on a separate branch if a chimeric flap is needed.
 - Dissect the pedicle from distal to proximal. Continue the dissection until

adequate pedicle length and vessel caliber has been obtained. One may encounter vascular branches to the vastus intermedius or rectus femoris, which can typically be sacrificed. Nerve branches should be spared.

- Ligate and divide the pedicle when the recipient area is ready.
- Perform your anastomosis and inset the flap.
- The anterolateral thigh (ALT) donor site can usually be undermined and closed primarily over closed suction drains. The maximum width of the flap is judged with a pinch test. Donor sites that cannot be primarily closed may be skin grafted. Others have reported closing large donor sites using adjacent tissue transfer techniques.

■ Gracilis

- Take into account all of the preoperative factors as noted in the preoperative planning section.
- Assess the defect.
- Approach your recipient vessel as mentioned in the various approaches above and dissect back to healthy vessel outside of the zone of injury. Use of tourniquet may be considered.
- Elevate the flap as previously described.¹⁵
 - With patient supine, position the lower limb in external hip rotation, and knee and hip in flexion as needed. Palpate the adductor longus tendon in the medial thigh.
 - The gracilis is posterior to the adductor longus. An incision is marked two to three finger breadths posterior to the adductor longus tendon. Keep in mind that the neurovascular pedicle enters the muscle approximately 10 cm below its bony origin.
 - An optional distal incision at the knee can be made to transect the distal tendon if the entire length of the flap is needed.
 - Carry the proximal incision down through the fat and muscular fascia to the muscle. Take care to identify the greater saphenous vein during this step and protect it by retracting if necessary.
 - Dissect superficial to the gracilis muscle to expose its surface.
 - Identify the interval between gracilis and adductor longus. Enter the interval carefully to identify the pedicle—the medial circumflex femoral artery and veins.

- Dissect the pedicle from distal to proximal. Continue the dissection until adequate pedicle length and vessel caliber has been obtained. One may encounter vascular branches to the adductor longus, which can be sacrificed. Nerve branches should be spared.
- Divide the muscle along the required dimensions. Ligate and divide the pedicle when the recipient area is ready.
- Perform your anastomosis and inset the flap.
- Harvest split-thickness skin graft for the flap.
- The donor site can usually be closed primarily over closed suction drains.

■ Rectus Abdominis

- Take into account all of the preoperative factors as noted in the preoperative planning section.
- Assess the defect.
- Approach your recipient vessel as mentioned in the various approaches above, and dissect back to healthy vessel outside of the zone of injury.
- Elevate the flap as previously described.¹⁶
 - With the patient supine, the muscle can be exposed through a midline vertical, paramedian vertical, or lower transverse incision with the total length of the incision depending on the amount of muscle harvested.
 - Dissect down to the level of the rectus sheath, ligating perforators as they are found.
 - Divide the rectus sheath longitudinally and elevate the fascia medially and laterally taking care to tease off the inscriptions without damaging the muscle fibers.
 - Identify the deep inferior epigastric artery and its accompanying veins at the lateral edge of the inferior muscle within the fatty tissue. Dissect the pedicle from distal to proximal. Continue the dissection until adequate pedicle length and vessel caliber has been obtained.
 - Divide the muscle along the required dimensions. Ligate and divide the pedicle when the recipient area is ready.
- Perform your anastomosis, and inset the flap.
- Harvest split-thickness skin graft for the flap.
- Close the fascia with nonabsorbable suture. Close the donor site wound primarily. Use drains as needed.

■ Latissimus Dorsi

- Take into account all of the preoperative factors as noted in the preoperative planning section.
 - Assess the defect.
 - Approach your recipient vessel as mentioned in the various approaches above, and dissect back to healthy vessel outside of the zone of injury.
 - Elevate the flap as previously described.¹⁷
 - The flap harvest is usually done in lateral decubitus position with appropriate padding. The ipsilateral arm may also be prepped into the operative field depending on surgeon preference. The current authors prefer to use a padded and draped Mayo stand to position the arm.
 - The latissimus is marked by finding the surrounding landmarks—scapular tip superiorly, iliac crest inferiorly, spinous processes medially.
 - Choice of skin incision also depends on surgeon preference and size of flap needed. Incisions made include transverse (to hide within a bra line), oblique (extending from posterior axillary fold over the middle of the muscle belly), or vertical (uncommon).
 - Expose the latissimus by dissecting the skin and subcutaneous tissues off the muscle all the way to all its edges. Dissect the submuscular plane taking care not to elevate the serratus muscle or fat pad. It is easiest to begin this dissection anteriorly or superiorly.
 - Release the insertions near the midline of the back and then inferiorly. Proceed with the submuscular dissection from distal to proximal toward the axilla. The pedicle can be visualized along the deep surface of the muscle as one approaches the axilla.
 - Identify the branch to the serratus muscle. Ligate it if necessary. The circumflex scapular branch may also be ligated if additional pedicle length or larger caliber is needed.
 - Trim the muscle along the required dimensions. Ligate and divide the pedicle (including the thoracodorsal nerve) when the recipient area is ready.
 - Reposition the patient if necessary.
 - Perform your anastomosis and inset the flap.
 - Harvest split-thickness skin graft for the flap.
 - Close the donor site over suction drains.
-

PEARLS AND PITFALLS

Amputation vs limb salvage	■ Consider limb salvage on a case-to-case basis. If a long, protracted course for limb salvage is anticipated, consider the benefit of early mobilization and physical therapy after amputation.
Zone of injury	■ Microsurgical anastomosis outside the zone of injury is critical to success.
Timing of reconstruction	■ If possible, reconstruction within 7 days in the acute period leads to higher incidence of flap survival.
Sequence of salvage	■ Bony stability, thorough debridement to achieve favorable wound bed, flap reconstruction.
Flap selection	■ Select a flap with sufficient pedicle length to anastomose outside the zone of injury, does not require intraoperative repositioning, and has acceptable donor site morbidity.

POSTOPERATIVE CARE

- Immobilization of the extremity and bed rest is recommended for 5 to 14 days postoperatively.
- Dangling of the leg is then initiated, with increasing frequency and length continuously while the flap is carefully watched for swelling, congestion, or increasing pain.
- Compression stockings or wraps are applied after 4 weeks and continued for approximately 6 months.

OUTCOMES

- The goal is a healed wound, return to activity, and acceptable contour (**FIG 5**).
- Functional outcomes largely depend on the extent of the patient's injuries.
- Prognosis for bony union and adequate neurovascular recovery must be considered.
- Patient compliance is important for best long-term results.
- Patients at high risk for amputation can be advised that reconstruction typically results in 2-year outcomes equivalent to those of amputation.¹⁸

FIG 5 • The goal is a healed wound, return to activity, and acceptable contour.

COMPLICATIONS

- Osteomyelitis
- Chronic pain
- Nonunion
- Flap failure
- Contour abnormality
- Donor site morbidity
- Amputation

Vascular Reconstruction of Lower Extremity, Foot, and Ankle

17

CHAPTER

Michael Sgroi and Jason T. Lee

DEFINITIONS

- Peripheral arterial disease (PAD) affects 8 to 12 million people worldwide.
- Up to 40% of these patients suffer from poor quality of life due to impaired walking ability, nonhealing wounds, and need for amputation.
- Risk factors include male gender, age, hypertension, diabetes, hyperlipidemia, renovascular disease, and smoking.
- Sixty to ninety percent of patients with peripheral arterial disease also have coronary artery disease, and up to 25% have carotid artery stenosis.¹
- The overall 5-year mortality rate among all patients with PAD is 15% to 30%, and the risk of nonfatal myocardial infarction or stroke is 20% at 5 years.²
- Patients with critical limb ischemia have an annual cardiovascular mortality of 25% and an annual amputation rate of 25%.³

ANATOMY

- Femoral artery usually lies one-third the distance from the pubic tubercle and two-thirds from the anterior superior iliac spine.
- Lateral dissection at the femoral artery should be minimized so not to disrupt the femoral nerve.
- Medial dissection at the femoral artery should be minimized so not to damage the femoral vein.
- Exposure of the common femoral artery should include the distal external iliac artery under the inguinal ligament.
- Care should be taken to identify all distal branches (superficial femoral artery (SFA) and profunda femoris).

- Anterior tibial artery runs in the anterior compartment of the leg.
- Anterior tibial artery is between the anterior tibialis and extensor digitorum longus muscles.
- Anterior tibial artery becomes the dorsalis pedis when it crosses the ankle joint.
- Dorsalis pedis can be palpated just lateral to extensor hallucis longus on the dorsum of the foot.
- Posterior tibial artery carries blood through the posterior compartment of the leg and plantar surface of the foot.
- Posterior tibial artery branches into the medial and lateral plantar arteries in the foot.
- Posterior tibial artery can be palpated midway between the medial malleolus and the Achilles tendon.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Ischemic claudication (ie, arterial perfusion inadequate to meet the demands of the muscle) leads to cramping, aching pain.
- Claudication will usually occur one vascular level below the stenosis or occlusion.
- Ischemic rest pain (ie, chronic ischemic neuropathy that is positional) is often described as diffuse aching or burning while legs are up in recumbent position, which is improved after legs have been put in the dependent position.
- Vascular and neurogenic claudication must first be differentiated.
- Infrapopliteal disease is most often going to lead to ankle and foot disease.
- Patients with tibial disease are more likely to experience rest pain or have nonhealing wounds rather than claudication symptoms.
- Ulcers to the medial side of the ankle are more likely due to venous disease.
- Ulcers to the lateral foot and ankle are more likely to be due to arterial disease.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- An ankle-brachial index (ABI) may be obtained by dividing the systolic blood pressure of the lower leg/ankle by the systolic blood pressure of the upper arm (brachial artery) (**FIG 1**).
- An $ABI \leq 0.9$ is considered abnormal.
- ABIs will most commonly be indeterminate because the tibial vessels

become noncompressible and waveforms will be monophasic.

- Toe-brachial pressures (TBIs) will be more diagnostic in patients with tibial disease.
 - A TBI < 0.4 will indicate a wound is unlikely to heal without intervention.
- Arteriography should be performed to evaluate the tibial vessels prior to any distal lower extremity or foot reconstruction.
 - Patients with diabetes and end-stage renal disease most frequently are affected by small vessel disease, including tibial vessels and the microvascular circulation.

FIG 1 • Example of an abnormal ankle-brachial index study.

SURGICAL MANAGEMENT

- A patient must first have an appropriate inflow and outflow vessel identified for reconstruction.
- Autologous vein has superior rates of patency compared to prosthetic grafts.
- Vein mapping should be performed preoperatively, assuring at least a 3-mm conduit.
- Shorter bypass grafts have better patency.
- The most distal patent native vessel should be used as the proximal origin of the bypass graft.

- For example, if the patient has a patent popliteal artery, this should be chosen over a femoral artery.
- Primary patency (the patency of a graft without any adjunctive therapies to keep it open), secondary patency (the patency rate once the graft has been completely abandoned and no further interventions are performed to keep it open), and limb salvage rates are 56.8%, 62.7%, and 78.2%, respectively, at 5 years for pedal revascularizations.

TECHNIQUES

■ Femoropopliteal Bypass

- Identification of the femoral artery should be within the femoral triangle.
 - Femoral triangle consists of the inguinal ligament superiorly, sartorius muscle laterally, and the adductor magnus medially.
 - The floor of the femoral triangle consists of the iliacus, psoas major, pectineus, and adductor magnus.
 - The femoral artery is a continuation of the external iliac artery below the inguinal ligament.
 - Common femoral artery divides into the profunda femoral artery and the superficial femoral artery.
 - The profunda femoral gives branches to the thigh and collaterals to the lower extremity.
 - The superficial femoral artery is a continuation of the common femoral artery and progresses to the popliteal artery.
- Longitudinal incision is made over the pulse in the groin, which is usually located below the inguinal ligament approximately one-third lateral to the pubic tubercle (**TECH FIG 1A**).
- Dissection is taken down through the fascia lata, keeping medial to the sartorius muscle (**TECH FIG 1B**).
- The superior limit of the groin dissection is the inguinal ligament. Retraction of the ligament exposes the external iliac artery.
- The inguinal ligament can be further retracted by laterally dissecting along the ligament releasing all attachments.
- Once under the ligament, the inferior epigastric vein should be identified and

ligated.

- Profunda femoral artery divides into the adductor fascia. Dissection along the anterior surface can be performed, identifying each of its branches (**TECH FIG 1C,D**).
- Care should be taken not to dissect into the deep lateral circumflex femoral vein, which lies across the proximal profunda.
- A lateral approach at the profunda can also be performed along the lateral surface of the sartorius.
 - The sartorius is then retracted medially while the rectus femoris and vastus medialis are retracted laterally.

TECH FIG 1 • **A.** Longitudinal exposure of the common femoral artery. **B.** A longitudinal incision is medial to the sartorius muscle allowing exposure. **C.** The femoral artery sits in the middle of the femoral sheath between the nerve and vein. **D.** Proper exposure includes vascular control of the common femoral, superficial femoral, and profunda femoral

artery.

Above-Knee Popliteal Exposure

- Exposure of the above-knee popliteal artery starts with a longitudinal incision on the distal medial thigh in the intermuscular groove between the sartorius muscle and the vastus medialis (**TECH FIG 2**).
- Care should be taken not to damage the greater saphenous vein during this incision.
- Sartorius is then retracted posteriorly, while the adductor magnus is retracted anteriorly.
- Retraction of sartorius and adductor magnus gives exposure to the adductor canal.
- Dissection is then performed through the popliteal fat pad allowing exposure of the popliteal artery and vein.

TECH FIG 2 • A. Exposure of the above-knee

femoropopliteal artery. **B.** Retraction of the sartorius muscle posterior and adductor magnus anterior allows for exposure of adductor canal. **C.** The geniculate collaterals should be saved if possible. However, they can be ligated for higher exposure if necessary. **D.** Adductor magnus can also be cut if needed for more proximal control.

Below-Knee Popliteal Exposure

- A longitudinal incision should be made on the medial calf from the tibial condyle distally (**TECH FIG 3A**).
- Keeping the medial head of the gastrocnemius posterior (**TECH FIG 3B**), the soleus muscle arch will be identified. Superior to the soleus is the popliteal fat pad where the popliteal neurovascular bundle is located.
- The paired popliteal veins will be surrounding the artery and will need to be mobilized (**TECH FIG 3C**).
- The soleus muscle can be dissected away from the tibia if more distal control is needed.
- Autogenous vein grafts provide the best patency for use in arterial bypass for all infrainguinal reconstructions, regardless of the distal bypass target.
 - Reverse and in situ vein have equal effectiveness.⁴
 - If an above-knee bypass is performed, PTFE has equivalent 2- to 3-year patency rates to autogenous vein.⁵

TECH FIG 3 • A. The below-knee popliteal artery is exposed from a medial incision starting at the tibial condyle and continuing distally. **B.** The medial head of the gastrocnemius muscle is then retracted posteriorly and popliteus muscle anteriorly. **C.** There are multiple crossing veins around the popliteal artery that will need to be controlled during popliteal artery exposure.

■ Vascular Reconstruction for Tibial-Peroneal Arterial Occlusive Disease

- Indications include rest pain, ischemic ulcerations, gangrene of the foot, and highly selected patients with short-distance claudication.
- Selection of conduit is most important. Autogenous vein should be used if possible. In general, adequate vein is larger than 3 mm.

- Ipsilateral vein is preferred over contralateral if possible.
- Inflow should be chosen based on preoperative imaging as well as available conduit length.
- Inflow vessels include common femoral, profunda femoris, superficial femoral artery, and above-knee popliteal artery.
- Outflow vessel chosen for bypass should be the one with in-line flow to the pedal vessels. However, peroneal can also be used despite lack of direct communication.

Anterior Tibial Artery Exposure

- Longitudinal incision lateral aspect of leg between the anterior tibialis and the extensor digitorum longus muscles.
- Dissection should be continued on the lateral aspect of the anterior tibialis muscle rotating it anterior and medial. The neurovascular bundle will be identified posterior to this muscle.
- Tunneling can be performed from a medial or a lateral approach.
- For a medial approach, a medial incision is made to expose the popliteal fossa. This is followed by an incision of the interosseous membrane to cross the conduit into appropriate position.
- If a lateral approach is used, then the graft is initially brought subsartorius from the femoral position and lateral through the tensor fascia lata. The tensor fascia will need to be incised to allow the conduit to come through. The graft will then lie in the subcutaneous tissue of the lateral thigh and calf.⁶
- Care should be taken with the lateral tunneling away from the fibular head to avoid injury to the peroneal nerve.

Posterior Tibial Artery Exposure

- Longitudinal incision is made 2 cm below the medial edge of the tibia.
- The gastrocnemius muscle is kept posterior until the soleus muscle is identified.
- Careful dissection is then performed with electrocautery dissecting the soleus off of the posterior tibia aponeurosis.
- Crossing tibial veins will need to be identified and ligated to allow the posterior tibial artery to be exposed.
- Tunneling for a posterior tibial bypass will be in the same anatomic position as a femoral popliteal artery bypass but extended down to the location of the

distal exposure.

Peroneal Artery Exposure

- Longitudinal incision on the medial leg 2 cm below the medial edge of the tibia
- The gastrocnemius and soleus are dissected posteriorly to expose the flexor digitorum longus muscle, which lies on the posterior aspect of the tibia.
- The fascia of the flexor digitorum longus is opened to enter the deep compartment. Dissection is carried until the peroneal vascular bundle is identified on the anterior aspect of the fibula on the flexor hallucis longus muscle.

Pedal Artery Exposure

- Exposure of the pedal vessels can be accurately identified with the assistance of ultrasound or handheld Doppler prior to making an incision.
- The dorsalis pedis artery will be on the dorsum of the foot just lateral to the extensor hallucis longus tendon.
- A longitudinal incision is made directly over the artery. Dissection will go through the dorsal sheath, and retracting the tendon medially should expose the dorsalis pedis.
- For the posterior tibial artery distally, a longitudinal incision is made half way between the medial malleolus and the Achilles tendon (**TECH FIG 4**).

TECH FIG 4 • Plantar exposure of the posterior tibial artery. Incision is made posterior to the medial malleolus. As the artery starts to cross the arch of the foot, it will branch into the medial and lateral plantar arteries.

PEARLS AND PITFALLS

Conduit condition

- If performing a vein bypass, always ensure careful handling of the venous conduit. If there is an area that appears sclerotic or injured, it is better to remove that segment.

Conduit length

- Obtain exposure of the proximal and distal location of your bypass prior to performing the vein harvest, as you want to make sure you have adequate length vein as well as an appropriate location for your

	proximal and distal anastomosis.
	■ Measure the distance of the bypass with the knee extended to ensure adequate conduit length.
Tourniquet use	■ A tourniquet can be used for arterial control of the distal anastomosis and is particularly useful if the patient significantly calcified vessels.
Imaging	■ A completion arteriogram is helpful if there is any question about the patient's outflow.

POSTOPERATIVE CARE

- Average length of stay for a bypass patient is 4 to 6 days.
- Leg elevation postoperatively is important as the patient will have swelling to the limb from both reperfusion and resection of the superficial venous system.
- All patients should be started on a daily 81 mg aspirin following surgery. Patients should also be restarted on their statin and beta-blocker if on them preoperatively.^{1,7}
- Dual therapy with antiplatelet and anticoagulation has demonstrated improved patency, particularly in patients who have a prosthetic conduit. However, these patients are also at increased risk of bleeding.
- Repeat ABIs with graft duplex can be performed at the first postoperative clinic visit in 2 to 4 weeks.

OUTCOMES

- Open surgical bypass is accepted as the most durable treatment for critical limb ischemia.
- Five-year overall patency rates range from 60% to 80% and limb salvage rate of 80% to 90% in patients with critical limb ischemia.
- Venous conduits have better patency than using prosthetic graft below the knee.
- Five-year expected patency rates for infrainguinal bypass a vein conduit^{4,8}
 - Femoral to above-knee popliteal—75%
 - Femoral to below-knee popliteal—70%
 - Femoral to tibial artery—65%
- Five-year expected patency rates for infrainguinal bypass with prosthetic graft^{5,8}
 - Femoral to above-knee popliteal—50%
 - Femoral to below-knee popliteal—35%

- Femoral to tibial artery—20%

COMPLICATIONS

- Patients with vascular disease often have other comorbid conditions. Systemic complications such as MI, stroke, renal failure, and pneumonia are all potential risks.
- Wound complications can occur with either incision but are particularly higher at the groin incision. Femoral incision complications occur in about 15% to 30% of patients, with underlying graft infection ranging from 1% to 7% depending on if autogenous vein or prosthetic graft were used.
- Early graft failures could be multifactorial.⁹
 - Technical failure due to imperfect anastomosis, or kinking of the conduit due to compression or graft redundancy.
 - Patients may have an undiagnosed hypercoagulable state.
 - Poor inflow. If depressed velocities with poor waveforms are seen in the conduit, further evaluation prior to the graft failing should be performed.

18 Management of Diabetic Foot Ulcers

CHAPTER

Rahim Nazerali

DEFINITION

- Foot ulcers are the most common complication affecting patients with diabetes mellitus.¹
- A result of lower extremity neuropathic disease, trauma, and deformity.
 - May be compounded by ischemia, callus formation, and edema.

ANATOMY

- Resembles laceration, puncture, or blister with round or oblong shape.
- May be necrotic, pink, or pale with well-defined smooth edges.
- Peri wound often presents with callus.

PATHOGENESIS

- Origin and development have several components.
- Thirty-two unique casual pathways for developing foot ulcers.²
 - Peripheral neuropathy, structural foot problems, and minor trauma are present in the majority (63%).
 - Other less prevalent causes include edema, callus, and peripheral ischemia.
- Major common pathways involve pressure/trauma, ischemia/hypoxia, infection, cellular failure, and chronic inflammation.

NATURAL HISTORY

- 12.5% individuals with diabetes will develop lower extremity ulceration.³

PATIENT HISTORY AND PHYSICAL FINDINGS

- Basic history, including state of health, record of diabetic complications, shoe problems, pain in extremity, medications, glycated hemoglobin level.

- Risk factor assessment involving absence of protective sensation due to peripheral neuropathy, vascular insufficiency, structural deformities/callus formation, autonomic neuropathy, limited joint mobility, long duration of diabetes, long history of smoking, poor glucose control, obesity, impaired vision, past history, increased age, male gender, poor footwear.
- The Wagner scale for foot wound classification based on depth and presence of osteomyelitis and gangrene is the most widely accepted classification scheme⁴ (**FIG 1**) but does not address the critically important parameters of ischemia and infection.
 - Grade 0: intact skin
 - Grade 1: superficial without penetration of deep layers
 - Grade 2: deeper reaching tendon, bone, or joint capsule
 - Grade 3: deeper with abscess, osteomyelitis, or tendonitis extending to those structures
 - Grade 4: gangrene of some portion of the toe, toes, and/or forefoot
 - Grade 5: gangrene involving the whole foot or enough of the foot that no local procedures are possible
- Physical exam:
 - Adequate description of ulcer characteristics such as size, depth, appearance, location, etc.
 - Examine with blunt sterile probe to detect sinus tract, undermining and dissection into tendon, bone or joints

FIG 1 • Wagner scale for foot wound classification showing the natural history of dysvascular foot breakdown.

- Identify limb-threatening infection defined by cellulitis extending beyond 2 cm from perimeter, abscesses, or osteomyelitis
- Protective sensation testing with Semmes-Weinstein 5.07 (10-g) monofilament test or vibration tuning fork test (128 cycles per second) with on-off method
- Evaluate for musculoskeletal abnormalities that lead to focal areas of high pressure
- Vascular status evaluation via segmental pressures, toe pressures, or transcutaneous oxygen readings
- Evaluate skin and nail condition of the affected extremity
- Footwear evaluation including bulges on outside of shoes, wear patterns on soles, wearing down heels, worn lining, shoe cushion, and foreign object in shoe

IMAGING

- Duplex studies: ABI/TBI (ABI can be falsely elevated due to atherosclerotic hardened vessels.)
- X-ray, MRI, or bone biopsy to rule out osteomyelitis
- Lower extremity angiography

DIFFERENTIAL DIAGNOSIS

- Peripheral neuropathy

NONOPERATIVE MANAGEMENT

- Early prevention through careful and frequent inspection is important.
- Key therapeutic objectives include addressing global factors (glycemic control and nutritional support) and local factors.
- Aggressive treatment of infection through targeted antibiotic treatment from tissue cultures.
- Establishing if ischemia is present and revascularization is required.
- Topical wound care by optimizing wound bed moisture balance and exudate/odor control.
- Off-loading and redistribution of pressure involving bed rest, wheelchairs,

crutches, surgical shoes, custom sandals, healing shoes, cast shoes, and foam dressings.

- Pressure relief of plantar ulcers utilizing orthotics and total contact casting, which is considered the “standard” treatment for off-loading
- Adjunctive hyperbaric oxygen treatment can be an important aspect of the treatment armamentarium. Cochrane Review supported a 95% reduction in major amputations when adjunctive HBOT (Hyperbaric Oxygen Therapy) was used to treat chronic diabetic foot ulcers.⁵
- Patient has type 1 or type 2 diabetes and has a lower extremity wound.
- Wound is classified as Wagner grade 3 or higher.
- Failed adequate course of standard wound therapy.

SURGICAL MANAGEMENT

- Ensure appropriate blood flow prior to surgical management.
 - Stenting vs bypass coordinated with vascular surgery

TECHNIQUES

■ **Aggressive Wound Debridement**

- Initial surgical debridement
 - Removal of free-living bacteria and biofilms
 - Stimulation of growth factors, removal of senescent cells, and removal of hyperproliferative nonmigratory tissue
- Maintenance of surgical debridement
 - Weekly debridement depending on the formation of new necrotic tissue.
 - First 4 weeks of treatment reduces median wound area by 54%.

■ **Flaps and Grafts**

- Local flaps and grafts described elsewhere in this text can be used for definitive soft tissue coverage.
-

PEARLS AND PITFALLS

Blood flow	■ It is critical prior to any surgical intervention that blood flow/perfusion be determined and optimized.
Adequate debridement	■ Ensuring adequate debridement of soft tissue and bone is critical to minimize biofilm and senescent cells.
Off-loading	■ Minimizing pressure to the area of a diabetic foot ulcer helps ensure adequate perfusion.
Infection control	■ It is important to address subclinical infections as well as ensure that the underlying osteomyelitis is appropriately treated for the successful long-term treatment of diabetic foot ulcers.
Consideration for hyperbaric oxygen	■ Studies indicate that Wagner grade 3 wounds benefit from hyperbaric oxygen therapy.

OUTCOMES

- 85% of lower limb amputations in diabetics are preceded by unhealed ulceration.
- 50% to 75% of lower extremity amputations are caused by nontraumatic amputations.
- Five-year mortality after amputation in diabetics is 45%.

Nerve Repair and Reconstruction—Peroneal Nerve

19

CHAPTER

Shawn Moshrefi and Catherine M. Curtin

DEFINITION

Peroneal Nerve Injury

- Peroneal nerve injuries vary in severity, mechanism, and needed treatment.
- The nerve injury type dictates the treatment and prognosis.
- Types of nerve injury¹
 - Neuropraxia: conduction delay with no axonal injury. These injuries will recover spontaneously without intervention.
 - Axonotmesis: axonal injury resulting in disruption of the axons; however, the supporting nerve scaffolding is intact. In these injuries, distal nerve segment will undergo Wallerian degeneration and proximal fibers will regenerate. Spontaneous recovery is possible.
 - Neurotmesis: complete disruption of the nerve. In these injuries, spontaneous regeneration will *not* occur.
 - Neuroma in continuity: disruption of the axons though the scaffolding seems to be intact. However, at the injury site, there is internal fibrosis, which prevents axons from regeneration. In these injuries, spontaneous regeneration will *not* occur.
 - Mixture of injury types: nerve patterns can be complex, and one nerve can have several different levels of injury.

ANATOMY

- The common peroneal nerve fibers originate from L4 to S3 nerve roots (**FIG 1**).

- The common peroneal nerve branches from the sciatic nerve in the popliteal fossa.
- The motor component of the peroneal nerve innervates the anterior and lateral lower leg compartment muscles as well as some intrinsic muscles of the foot.
- The sensory component of the peroneal nerve supplies the first dorsal web space of the foot and the top of the foot.
- The peroneal gives off the lateral sural cutaneous branch, which joins the medial sural cutaneous branch (contributed from tibial nerve) to form the sural nerve.
- The common peroneal nerve crosses from posterior to anterolateral around the neck of the fibula.
 - The peroneal nerve is susceptible to compression as it wraps around the fibula.
- Once the nerve crosses anterior to the fibula, it branches into the superficial peroneal and deep peroneal nerves.
- The superficial peroneal nerve passes straight down the lateral compartment.
 - The superficial peroneal nerve supplies motor to the lateral compartment (peroneus longus and peroneus brevis).
 - The superficial peroneal nerve supplies sensation to the top/lateral portion of the foot.
- The nerve transitions from within the muscle to a more superficial subcutaneous position at the junction of the middle and distal thirds of the lower leg. This transition site can be a point of compression.
- The deep peroneal nerve turns acutely around the fibular neck to enter the anterior compartment of the leg. The deep peroneal nerve then passes under the intermuscular septum between the anterior and lateral compartments to eventually course down between the tibialis anterior and extensor hallucis longus alongside the anterior tibial artery.
 - The deep peroneal motor nerve supplies the anterior compartment of the leg as well as some of the small foot extensor muscles: tibialis anterior, extensor digitorum longus, peroneus tertius, extensor hallucis longus, extensor digitorum brevis, and extensor hallucis brevis.
 - The deep peroneal nerve supplies sensation to the first web space of the foot.

FIG 1 • Anatomy of the peroneal nerve.

PATHOGENESIS

- Direct trauma can injure the nerve along its course.
 - Fibular fracture can lacerate the nerve or result in neuropraxia.
 - Knee dislocation can result in a stretch injury or even a rupture of the peroneal nerve.²
 - Iatrogenic injuries that occur include prolonged tourniquet time, laceration of nerve during hardware placement, and compression of nerve from operative positioning.
- Swelling and compression can cause injury along the course of the peroneal nerve.
 - Ankle swelling can cause superficial peroneal nerve entrapment and resulting pain.

- Compression from tight splints or casts can result in common peroneal nerve injury.
- Soft tissue masses
 - Cysts, especially Bakers cysts, or other nerve compressing structures can result in peroneal nerve injury.
 - Neural tumors such as schwannomas can result in nerve deficits.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete and thorough history detailing patient's history of present illness, current injuries, history of prior injuries, prior surgeries (including spinal, buttock, and lower extremity procedures), comorbidities, occupation, and other case-by-case considerations should be obtained.
- Inspection
 - Is the leg/foot swollen?
 - Are there vascular changes?
 - Is there atrophy?
 - Is there a gait abnormality or foot drop?
- Vascular exam should assess for palpable pulses distally, temperature, and capillary refill of the foot.
- Sensory exam
 - Ten test: this quick test uses the contralateral area of normal sensation as a reference. The patient is lightly touched in the contralateral healthy distribution, and this normal sensation is a "ten." Then, both the healthy and affected side are lightly touched at the same time, and the patient is asked to grade the affected side using the scale 0 to 10.³
- Motor exam
 - Consists of testing the respective muscles that the peroneal nerve: extension of the foot and ankle.
 - Each muscle can be tested individually and compared to the contralateral side. Comparing to the healthy side allows for identification of subtle motor deficits seen in compression.
 - Motor examination remember mnemonic PED = **P**eroneal **E**verts and **D**orsiflexes or more correctly noted, Extends.
- Scratch collapse test⁴
 - This test can identify site of nerve entrapment.

FIG 2 • Large peroneal nerve schwannoma.

- Directly over the suspected nerve compression, the examiner gently scratches the skin. Then, the examiner immediately tests *arm* external rotation by applying force to the patient's dorsal forearm. The patient attempts to resist.
- A positive test on the scratch collapse test is when the patient briefly has decreased external rotation strength and “collapses” under the examiner's pressure.
- Tinel test

IMAGING

- X-rays are useful for suspected bony injury.
- Angiography may be required in complex trauma patients.
 - This is particularly important as the deep peroneal nerve runs intimately with anterior tibial artery.
- MRI
 - Standard MRI can assess for soft tissue masses such as Baker cysts, schwannomas, or tumors.
 - **FIG 2** shows a large peroneal nerve schwannoma with its typical smooth bright appearance.
 - MRI neurogram can identify areas of nerve compression and enhancement (**FIG 3**).
 - Nerve conduction studies and electromyelography.
 - For acute injuries, perform the first nerve testing at least 1 month after injury.
 - Studies can be repeated at 12 weeks, if there is no signs of recovery on physical examination.

- Nerve conduction studies may be normal for nerve compression that has not resulted in any axonal injury.

FIG 3 • MRI showing inflamed deep peroneal nerve and superficial peroneal nerve.

DIFFERENTIAL DIAGNOSIS

- Lumbar spinal pathology
- Sciatic pathology
 - If on physical examination, both peroneal nerve and tibial nerve distributions are involved, then sciatic pathology should be suspected.
 - Nerve studies should help differentiate.
- Neurologic problem
 - Peripheral neuropathy
 - Motor neuron disease
- Double crush⁵
 - A nerve may have more than one site of entrapment: for example, common peroneal at the fibular head and superficial peroneal at middle third of lower leg.
 - The theory is that an axon injured in one area may be more susceptible to secondary sites of injury.
 - Missing secondary sites of pathology will result in limitation of recovery if only one site is treated.

NONOPERATIVE MANAGEMENT

- For closed nerve injuries, nonoperative management is appropriate initially.

- Physical modalities
 - Edema prevention with lightly compressive wraps/garments and direct hands on physical therapy can be helpful.
 - Strategic splinting to prevent contractures.
 - Ankle-foot orthoses help improve mobility and stability in patients with a foot drop.
 - Gentle range of motion exercises to allow the nerve to glide and limit potential scarring in an injured soft tissue bed.
 - Desensitization to minimize pain and reeducate the nociceptive pathways.

SURGICAL MANAGEMENT

- Exploration and repair is indicated for open nerve injuries or closed injuries that are not showing signs of recovery.
- Nerve laceration
 - Urgent repair is indicated.
- Blast injuries should be explored no sooner than 6 weeks.
 - These injuries can have a surprising amount of recovery and should be followed until recovery plateaus before surgery.
 - Intraoperative nerve monitoring is critical to define the zone of injury.
- Traction injury should be explored if no signs of recovery at 3 months.

FIG 4 • Patient positioning for decompression of common peroneal and superficial peroneal nerves.

- Intraoperative nerve monitoring is critical to define the zone of injury.
- Be prepared for the need for long nerve grafts.

- Release of compressed common peroneal nerve (or branches) can be performed after thorough workup and no signs of recovery at 3 months.
- If injured superficial peroneal nerve resulting in painful neuroma in ankle or foot region, consider resection of nerve at junction of middle/distal third of the leg.
 - This will trade numbness for pain.
 - It will allow the surgeon to be out of the zone of injury.
 - Allows new placement of the neuroma deep in muscle and not crossing a joint.

Preoperative Planning

- Definitive fracture fixation should be performed prior to nerve repair.
- Arterial injury should be addressed prior to nerve repair.
- If possible, use a lower extremity tourniquet to aid in visualization of the nerve.
- If intraoperative nerve monitoring to be utilized, inform anesthesia team to not use paralytics.
- If pain is a concern, consider a more aggressive perioperative pain strategy.
 - 900 mg of gabapentin preoperatively⁶
 - Intraoperative ketamine
 - Regional block
 - Multimodal postsurgical pain management strategy
- If planning nerve resection of superficial peroneal nerve
 - Preoperative diagnostic block of the nerve at planned level of resection.
 - Ensure patient has significant relief of pain for hour after block.
 - Ensure patient will tolerate the numbness felt at the time of the block for the decrease in pain.

Positioning

- Positioning depends on level of injury (above knee, at level of knee, or below knee).
- Access to popliteal area is easiest when the patient is in the prone position.
- Access to the lateral leg is managed either supine with a hip bump or a “sloppy” lateral with the unaffected side down. **FIG 4** shows positioning for decompression of common peroneal and superficial peroneal nerves.
- Access to compression sites at the extensor retinaculum is managed with the

patient supine.

TECHNIQUES

■ Common Peroneal Nerve Decompression

- Regional or general anesthesia
 - If no intraoperative nerve monitoring is required, regional anesthesia with a pain pump can provide several days of pain relief reducing opioid use.
- Thigh tourniquet is placed.
- Hip bump or slight lateral decubitus positioning to internally rotate the leg.
- Oblique incision 2 cm distal to the fibular head (on thin patients, you can palpate the nerve and design your incision above the nerve).
- Skin and subcutaneous tissue are divided down to the overlying fascia of the anterior lower leg muscles. Careful hemostasis is obtained as the dissection proceeds.
- Begin proximal and identify the nerve just posterior to the biceps femoris tendon.
 - The nerve is visualized with gentle longitudinal spread with a dissecting scissor.
- A vessel loop is placed around the nerve.
- The dissection proceeds distally releasing the fascia overlying the nerve. The fascia that overlies the muscles in the lateral muscle compartment is released. Then, the muscle fibers are spread/retracted allowing visualization of the thick fascia overlying the nerve, which is released (**TECH FIG 1**).
- The nerve will start dividing at the level of the fibular neck. In addition to the superficial and peroneal branches, the genicular branch that loops back proximal to the joint.
- Under direct visualization, follow the branches distally to ensure there are no unreleased fascial bands. The intermuscular septum can cause compression so inspect for any overlying compressive bands.
- This dissection can be performed with an incision that only goes about 2 cm anterior to the fibular head.
- Release tourniquet, achieve hemostasis, and close skin.
- Soft bulky dressing is placed.

TECH FIG 1 • Visualization of the peroneal nerve.

■ Common Peroneal Nerve Traction Injury (Knee Dislocation)

- General anesthesia is required as patient will be prone and intraoperative nerve monitoring will be used.
- Thigh tourniquet.
- Prone positioning.
- Intraoperative nerve monitoring available.
- Incision is angled from the center of popliteal fossa laterally toward the fibular head.
- The dissection is taken down to the level of the muscle fascia.
- The common peroneal nerve is identified as it branches off the sciatic nerve.
- A vessel loop is placed on the nerve, and the dissection is taken distally.
- The nerve is released from the overlying scar (often a very challenging dissection). The dissection is taken around the fibular head releasing the anterior muscle fascia.
- Intraoperative nerve monitoring is performed. Start with somatosensory evoked potentials can help establish the proximal level of intact nerve. Nerve-to-nerve monitoring can identify neuroma in continuity.
- If the nerve is ruptured or neuroma in continuity is identified, resect damaged nerve until two healthy nerve ends are revealed.
- Ensure that the proximal nerve is healthy by using the assistance of your neuromonitoring.

- For the nerve gap, harvest sural nerve graft.
 - Cable the graft and suture in place with a few 9-0 sutures using microscopic technique. The repair should be tension free to allow for knee motion.
 - Augment repair by sealing coaptation site with fibrin glue.
 - Close wound.
-

■ Superficial Peroneal Nerve Compression Release and/or Neurectomy

- Thigh tourniquet.
 - Regional anesthesia.
 - Supine position.
 - Approximately 3 cm longitudinal incision over seam between anterior and lateral compartments at juncture of middle and distal third of the leg.
 - The dissection is taken down to the level of the muscle fascia.
 - Identify the thin raphe located between the lateral and anterior compartments of the lower leg.
 - Of note, there is a wide fat stripe anterior to the superficial peroneal nerve. If you find this first, look about a 1 cm posterior and you will find the seam that contains the nerve.
 - Release overlying fascia proximally and distally.
 - If performing neurectomy for damaged superficial peroneal nerve, the approach to the nerve is the same.
 - Once the nerve is identified, divide nerve distally and free up the proximal nerve for several centimeters.
 - Place nerve stump deep within peroneus longus muscle. Bury the nerve stump in the muscle bed without tension.
 - Close wound and place bulky dressing.
-

■ Nerve Laceration

- The nerve is identified using the existing wounds or the approaches described above.
- The nerve can be directly coapted using microsurgical technique if a tension-free repair is possible.

- If there is tension, a bridging nerve graft is required.
- Nerve repair is done using microsurgical technique and should be tension free.
- Use 9-0 suture and the minimal amount of sutures needed.
- Fibrin glue can be used to seal the repair site and to hold cabled nerve grafts together.
- The wounds are closed.
- Repairs are protected for 3 weeks if concern about the repair with splints/braces to limit mobility at adjacent joints.

PEARLS AND PITFALLS

Nerve repair	■ Nerve coaptation must be without tension. If a 9-0 suture cannot hold the repair, there is too much tension and a graft is required.
Diagnosis of entrapment site	■ Confident location of entrapment can be made if the patient has a positive Tinel sign, positive scratch collapse, and sensory changes in the appropriate distribution. ■ Double crush is a risk so assess if nerve entrapped at both the superficial and common peroneal entrapment sites.
Intraoperative monitoring	■ Communication between neurology and anesthesia team is critical to ensure that patient does not receive medications that will hinder intraoperative monitoring. ■ SCD machine and warming machines can cause background that interferes with intraoperative monitoring. ■ Do not use prolonged tourniquet if planning intraoperative monitoring.
Meticulous hemostasis	■ If not using a tourniquet, preinject incision with bupivacaine with epinephrine before prepping. ■ To improve visualization, a mix of 1 ampule of epinephrine with 100 cc of saline can be used to moisten gauze pads. These can be dabbed in the wound and improve visualization and minimize the need for cautery adjacent to the nerve.

POSTOPERATIVE CARE

- Medications

- If neuropathic pain is a significant concern, consider multimodal pain control, which can include acetaminophen, NSAIDs, gabapentin, and opioids.⁶
- Therapy
 - At 2 to 3 weeks, consider therapy for scar management, nerve gliding, and desensitization.
- Nerve repair
 - Nerve repairs with slight tension need to be protected from disrupting forces for 3 weeks postoperatively. This can be performed through an immobilizer or splint. However, if reconstructed with a graft with some redundancy, early mobilization is possible.
- Nerve decompression
 - Soft dressing and early mobilization will prevent scarring and tethering of the nerve.

OUTCOMES

- Studies show approximate 80% functional nerve recovery in patients with a multitude of methods of common peroneal nerve injuries.⁷
- Other studies indicate a vastly significant difference in prognosis from incomplete nerve palsy (highly favorable functional outcome) to complete peroneal nerve palsy (less than 40% functional recovery).²
- Complete peroneal nerve injuries after knee dislocation still have poor functional outcomes with less than 40% recovering extension despite treatment.²
- Release of the superficial peroneal nerve has resulted in high rates of pain resolution.^{8,9}

COMPLICATIONS

- Most severe complication is iatrogenic nerve injury though this is very rare
- Bleeding
- Infection
- Fibrosis of the release site requiring revisionary surgery

20 Achilles Tendon Reconstruction

CHAPTER

Hani Sbitany

DEFINITION

- Achilles tendon is the most frequently ruptured tendon in the body, with incidence reported as high as 34/100 000, most commonly seen in males in their 30s.¹
- The male-to-female ratio of this injury is 20:1.
- Classically seen when less active males engage in a new sport, without significant previous experience.

ANATOMY

- Most common site of rupture is 3 to 6 cm above the os calcis (ie, the calcaneus):
 - This area is a watershed zone in terms of blood supply.
- Achilles tendon is made up of gastrocnemius and soleus muscles, along with the plantaris tendon (**FIG 1**).
- This tendon begins in the midportion of the calf (superficial posterior compartment) and narrows to approximately 4 cm width at its insertion on the calcaneus bone.
- Achilles tendon helps to produce plantar flexion of the foot, which is powered through associated muscle innervation by the tibial nerve.

FIG 1 • The Achilles tendon is formed by the convergence of the medial, lateral gastrocnemius, and soleus muscles.

PATHOGENESIS

- With aging, there is an increase in type 3 collagen content on the Achilles tendon and a reduction in type 1 collagen content.²
- Increasing age is also accompanied by decreased orderly collagen cross-linking.
- All this results in reduced tensile strength of the tendon.

NATURAL HISTORY

- In addition to aging, there are numerous other risk factors associated with Achilles tendon rupture:

- Hypercholesterolemia
- Rheumatoid arthritis
- Hypercholesterolemia
- Long-term dialysis
- Renal transplantation
- Chronic steroid use

PATIENT HISTORY AND PHYSICAL FINDINGS

- A history of pain and weakening on plantar flexion is usually indicative of Achilles tendon rupture.
- On physical exam, there is usually a palpable defect in the tendon, in 75% of patients.
 - Up to 25% of tendon injuries can be missed when only clinical assessment is used for diagnosis.
- Simmonds/Thompson test: the patient lies face down with feet hanging off the edge of the bed. If there is no plantar flexion of the foot on squeezing the calf, then there is likely rupture of the Achilles tendon.
- O'Brien test: insert 25-gauge needle at right angle through the skin of calf muscle just medial to midline at a point 10 cm proximal to superior border of calcaneus. The needle should be within the substance of the tendon. Movement of the needle in a direction opposite that of the tendon during passive extension and flexion of the foot confirms an intact tendon distal to the level of needle insertion.
- Copeland test: the patient is prone with the feet hanging off of the exam table. A sphygmomanometer is placed around the calf with the foot in plantar flexion and inflated to 100 mm Hg. If the tendon is intact, then extension of the foot will lead to a pressure increase to 140 mm Hg. If the tendon is ruptured, then the pressure does not change.

IMAGING

- Imaging is always recommended when there is clinical concern for Achilles tendon rupture.

FIG 2 • A. Normal Achilles ultrasound image. **B.** Ankle MRI (T1-weighted image) showing a distal Achilles tendon rupture. (From Labib S. Open Achilles tendon repair. In: Wiesel S, ed. *Operative Techniques in Orthopaedic Surgery*. 2nd ed. Vol. 4. Philadelphia, PA: Wolters Kluwer Health; 2015:4967-4973.)

- Ultrasound is a useful first-line imaging technique, with sensitivity of 100% (**FIG 2A**).
- Ultrasound tendon gap greater than 4 mm with patient in equinus (plantar flexion) indicates the need for surgical repair.
- Ultrasound can differentiate partial vs complete tear:
 - This is more difficult with a tear at the proximal musculotendinous junction, in which sensitivity is much lower.
- MRI is the best imaging modality for Achilles tendon rupture, with sensitivity of 100% (**FIG 2B**).
- MRI should always be obtained if any uncertainty exists regarding location, completeness, or length of tear.

DIFFERENTIAL DIAGNOSIS

- Achilles tendon peritendinitis
- Gastrocnemius tear or strain
- Calcaneus fracture
- Posterior tibialis tendon injury
- Posterior tibialis stress syndrome

NONOPERATIVE MANAGEMENT

- Nonoperative treatment of Achilles rupture is only an option in cases of acute rupture, with immediate diagnosis.
 - In cases of delayed diagnosis, scarring and retraction of tendon ends make conservative management less effective and unlikely to heal properly.
- The purpose of nonoperative management is to appose the ruptured Achilles ends, in stable fashion, such that healing can occur.
- Treatment regimen consists of immobilizing the extremity below the knee, with a brace or rigid cast.
 - The foot is initially placed in full plantar flexion.
 - Ankle is slowly brought into neutral position over 8 to 12 weeks.
- Knee immobilization is not necessary for reapproximation of the tendon edges.
- Early, gradual weight bearing has also been shown to confer protection against repeat rupture in the future.
- Many nonoperative regimens now advocate early weight bearing in a custom or Sheffield splint.
 - This is particularly beneficial in frail patients for whom joint contracture is at high risk.
 - The Sheffield splint is a specialized device worn on the lower leg and foot that allows for early controlled mobilization of the Achilles tendon.
- Early weight bearing also facilitates faster resumption of mobility after complete healing.
- One preferred conservative regimen:
 - Patient in full equinus (30 degrees) with touch weight bearing for 2 weeks
 - Ankle then placed in partial equinus (15–20 degrees) with partial weight bearing for 2 weeks
 - Finally, placed in neutral (0 degrees) with full weight bearing for 2 weeks

SURGICAL MANAGEMENT

- Operative treatment is used for the majority of acute tendon ruptures in younger patients, as well as in all patients with chronic rupture or delayed diagnosis.
- This is the only treatment option when there has been scarring and retraction of the tendon ends, resulting in a lack of apposition.

Preoperative Planning

- As previously mentioned, ultrasound and MRI assessment of the injury is important, to identify the location of the rupture relative to the musculotendinous junction and the length of the gap.
- The patient's physical examination should also include a workup of mobility potential and strength, to ensure that early mobilization and weight bearing will be possible.

Positioning

- Surgical repair is commonly performed with the patient in the supine position, the hips abducted, and the knees flexed (frog leg position) (**FIG 3**).
- The operation can also be performed with the patient in the prone position, for easier, direct access to the posterior ankle.

Approach

- Open surgical repair is performed with a direct longitudinal incision, directly over the Achilles to expose the entire tendon.

FIG 3 • Patient is placed in the prone position with both legs prepared and draped for surgery. (From Labib S. Open Achilles tendon repair. In: Wiesel S, ed. *Operative Techniques in Orthopaedic Surgery*. 2nd ed. Vol. 4. Philadelphia, PA: Wolters Kluwer Health; 2015:4967-4973.)

■ Percutaneous Repair

- Performed with patient in prone position.
- Skin incision is first made over site of rupture.
- Second skin incision made 4 cm proximal to initial incision.
- Third incision made 4 cm distal to rupture (**TECH FIG 1A**).
- The track of the entire tendon is defined under the skin and spread open.
- For this repair, a suture is first passed on a needle through middle incision and through tendon at this point (**TECH FIG 1B**).
 - A monofilament, permanent suture is used for this.
- Needle is then passed proximal and brought out through proximal incision (see **TECH FIG 1B**).
 - At this proximal incision, the suture is then passed through the proximal cut edge of the Achilles tendon.
- The needle is then passed back through the tunnel, brought out the middle incision, passed through the distal stump of the tendon, and brought out the distal end (**TECH FIG 1C**).
- Traction is then applied to ensure proper tension (**TECH FIG 1D**).

TECH FIG 1 • A-D. Pattern for suture passage for percutaneous repair of Achilles tendon rupture.

■ Open Direct (End-to-End) Suture Repair

- Performed in cases of acute rupture, less than 6 weeks old.
- Achilles tendon exposed along the entire length through vertical skin incision.
- Multiple figure-of-8 sutures are used to repair tendon at proper tension (**TECH FIG 2**).
- Similar to percutaneous, a large monofilament, permanent suture is used for repair.

TECH FIG 2 • End-to-end suture repair of Achilles tendon rupture.

■ Reconstruction With VY Advancement

- Used to repair chronic ruptures with defect less than 3 cm between tendon

ends.

- The entire posterior compartment, from the calcaneus to the midportion of the calf, is exposed with the incision.
 - The gastrocnemius/soleus/Achilles junction is exposed posteriorly from the prone position.
 - An inverted V incision is planned along the posterior superficial surface of the muscular complex, with the apex of the V placed at the proximal portion of the myotendinous junction.
 - The medial and lateral limbs of the V exit through the sides of the Achilles tendon.
 - The inverted V is incised through the tendinous, superficial portions of the tissue, leaving underlying muscle intact.
 - Then, the tendon ends are sutured to each other across the rupture, using permanent suture.
 - Can use monofilament or braided suture.
 - Done with locking knots, at least five suggested.
 - Tension is set with gentle traction, such that the muscle is not disrupted.
 - Finally, the limbs of the inverted V are rerepaired with suture.
-

■ Flexor Hallucis Longus Transfer

- Used to repair chronic ruptures with defect greater than 3 cm between tendon ends.³
- Requires a functional tibial nerve.
- The flexor hallucis longus (FHL) tendon can be harvested through the same posterior Achilles incision used for injury exposure.
- The dissection is carried down into the deep posterior compartment fascia, and underneath this, the FHL muscle and tendon sit.
- The FHL muscle belly extends more distal than others in this compartment, usually to the level of tibiotalar joint, which is the method of identification:
 - The muscle is confirmed by retracting manually and seeing flexion of the hallux.
- Medial to the FHL tendon, the neurovascular bundle of tibial nerve and posterior tibial artery is identified.
- The muscle is dissected distally, around the medial malleolus, taking care not

to injury the neurovascular bundle.

- Then, the FHL is transected as distal as possible, along its tendinous portion, with the ankle held in flexion and muscle under traction.
- Based on FHL tendon diameter, a bone tunnel is drilled into the calcaneus (posterior tubercle), just anterior to the area of Achilles tendon insertion on the bone.
- The length of the FHL muscle and tendon is set, after the tendon is passed through the tunnel using a suture and passer (**TECH FIG 3**).
 - At this length, the tendon is fixed into the calcaneus after passing through the tunnel, with an interference screw.
- The final resting tension, after repair, is compared to the contralateral uninjured side.
- Gentle extension is applied to test the repair, and then the skin is closed.⁴

TECH FIG 3 • Flexor hallucis longus tendon used to augment Achilles tendon repair. (From Labib S. Open Achilles tendon repair. In: Wiesel S, ed. *Operative Techniques in Orthopaedic Surgery*. 2nd ed. Vol. 4. Philadelphia, PA: Wolters Kluwer Health; 2015:4967-4973.)

POSTOPERATIVE CARE

- For most repair techniques, the ankle is splinted in equinus for 2 weeks.
- Strict nonweight bearing is employed for 6 to 8 weeks.

- After 2 weeks, once the healing skin is confirmed on examination, the patient is converted to postsurgical boot that gradually allows for passive extension in increasing increments over the next 4 weeks.
- At 6 to 8 weeks, patient is examined and tested for Achilles repair persistence, and weight bearing is started in ankle boot brace.
 - Physical therapy also started at this point.
 - Three sessions of PT for 8 weeks.
 - PT focuses on passive Achilles stretching and gait training.
- At 12 weeks, if the ankle is neutral alignment on exam, the patient is allowed to resume activity slowly.

COMPLICATIONS

- Bleeding
- Infection
- Tendon rerupture

21 Excision of Soft Tissue Tumors of the Lower Leg

CHAPTER

Raffi S. Avedian and Robert J. Steffner

DEFINITION

- Soft tissue tumors of the lower leg may be benign or malignant (soft tissue sarcoma) and exhibit a variable natural history ranging from latency to rapid growth.
- Tumors located entirely above the muscle fascia are considered superficial, whereas tumors involving the fascia or deep to it are considered deep.

ANATOMY

- The lower leg is made up of the tibia and fibula and four muscle compartments: anterior, lateral, deep posterior, and superficial posterior (**FIG 1**).
- Three principal arteries travel in the lower leg.
 - The posterior tibial artery is located in the deep posterior compartment on the surface of the tibialis posterior.
 - The anterior tibial artery is in the anterior compartment located deep to the muscles on the surface of the interosseous membrane.
 - The fibular artery travels in the deep posterior compartment medial to the fibula under the flexor hallucis longus; it sends branches to the lateral and anterior compartments and a nutrient vessel to the fibula.
- The deep peroneal nerve travels with the anterior tibial artery. The superficial peroneal nerve is located in the lateral compartment; in the distal one-third of the leg, it travels between the peroneus muscles and extensor digitorum longus and pierces the deep fascia to become a cutaneous nerve.

FIG 1 • Cross-sectional anatomy of lower leg showing the contents of the anterior, lateral, superficial posterior, and deep posterior compartments.

PATHOGENESIS

- The mechanism for soft tissue tumor formation is not known.
- Risk factors for sarcoma development include radiation exposure, radiotherapy, pesticide exposure, and hereditary conditions including Li-Fraumeni syndrome and retinoblastoma gene mutation.

NATURAL HISTORY

- All soft tissue sarcomas have the potential for local recurrence and metastasis.¹
- Soft tissue sarcomas exhibit a spectrum of natural history from slow-growing low-grade tumors with low risk of metastasis to high-grade sarcoma that may grow rapidly and pose a high risk of metastasis.

- Lungs are the most common site of metastasis. Lymph node involvement is rare.
- Angiosarcoma, clear cell sarcoma, epithelioid sarcoma, rhabdomyosarcoma, myxofibrosarcoma, and synovial sarcoma are associated with increased risk of lymph node spread compared to other sarcomas.²
- Benign tumors by definition do not have metastatic potential but can grow to large sizes and cause symptoms.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and examination are important to assess duration of symptoms, comorbidities, physical dysfunction, organ involvement, overall health, and patient expectations in order to best tailor treatment strategy for the individual patient.
- Many sarcomas may be asymptomatic with the only patient complaint being the presence of a mass.
- Neurovascular examination is mandatory for any extremity tumor.

IMAGING

- Magnetic resonance imaging is the principal imaging modality used to characterize tumors, formulate differential diagnosis, define local tissue infiltration, and formulate surgical plan.
- Plain radiographs are used if there is concern for bone involvement or to demonstrate mineralization within a tumor such as vascular malformations.
- Staging for soft tissue sarcomas consists primarily of lung imaging.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis for a soft tissue tumor includes benign tumors, sarcomas, lymphoma, infection, and inflammatory lesions (eg, rheumatoid nodules).
- There are over 50 sarcoma subtypes. Common histology types include pleomorphic undifferentiated sarcoma, synovial sarcoma, leiomyosarcoma, malignant peripheral nerve sheath tumor, liposarcoma.

SURGICAL MANAGEMENT

- The appropriate treatment for any musculoskeletal tumor is based on its diagnosis and natural history.
- Biopsy incisions are considered contaminated and must be resected at the time

of definitive surgery. Care should be taken to place the biopsy in a location that does not interfere with the final surgical plan.³

- Simple marginal excision is appropriate for most benign tumors, and wide resection with a clean margin is performed for soft tissue sarcomas.
- Given the relatively low volume of tissue in the lower leg and ankle, soft tissue reconstruction with local or free flaps is often needed.

Preoperative Planning

- A patient is considered ready for surgery after completion of staging and multidisciplinary review of pertinent imaging, pathology, and treatment strategy.
- The surgical plan is created by thorough study of the preoperative MRI scan. Fluid-sensitive sequences and fat-suppressed contrast images show the extent of disease that must be accounted in the excision. T1 fat-sensitive images show the normal anatomy best including fat planes between tumor and critical structures such as nerves and vessels.
- When tumor abuts, but does not encase blood vessels or nerves, they can be dissected free by leaving adventitia and epineurium on the tumor as the margin.⁴

Positioning

- Patient positioning is based on the surgeon's assessment of the critical anatomy of the surgery and how best to visualize it during surgery.
- Supine is the most common position for tumor excision of the lower leg. A hip bump may be used to access more lateral tumors; conversely, frog legging the extremity facilitates medial and posterior visualization.
- If a flap is to be used, the harvest must be performed using a separate back table and instruments and the surgical sites completely isolated to avoid contamination.

Approach

- The surgical approach varies based on location of the tumor.
- Previous biopsy and surgical scars are considered contaminated and must be excised en bloc with the tumor.

TECHNIQUES

■ Excision of Soft Tissue Tumor of the Lower Leg

- Tourniquet is used at the discretion of the surgeon by using gravity exsanguination rather than Esmarch to avoid tumor compression and potential risk of tumor spreading.
- A skin incision is used to approach the tumor.
- Superficial sarcomas require a large paddle of skin to be excised on top of the tumor to serve as the superficial margin and the deep fascia with a small cuff of deep muscle to serve as the deep margin. Deep sarcomas can often be approached with a longitudinal incision, but more extensive soft tissue excision is done in the deeper layers.
- A unique consideration for the lower leg is the relatively smaller volume of soft tissue compared to the thigh. Even a medium-sized sarcoma, eg, 5 cm, will occupy a large proportion of the leg. After excision, there is typically a relatively large defect that will require free tissue transfer for soft tissue reconstruction.
- Benign tumors may be excised through a longitudinal skin incision and simple dissection along the margin of the tumor by leaving most of the native tissues in place (**TECH FIG 1**).

TECH FIG 1 • **A.** Axial T1 fat-suppressed contrast MRI showing a tumor in the anterior compartment of the lower leg between the tibialis anterior and extensor digitorum longus. Biopsy confirmed benign schwannoma. **B.** Coronal view demonstrating craniocaudal extent of tumor. **C.** Intraoperative photograph showing dissection through deep fascia and separation of the tibialis anterior and extensor digitorum. Simple dissection around the tumor capsule was performed to deliver the tumor. **D.** Excised specimen on the back table. **E.** Photograph showing the defect after excision. Because the native muscles were not excised, a primary closure was possible.

PEARLS AND PITFALLS

Wound breakdown

- Dead space after tumor removal should be managed with drains, muscle flap, free tissue transfer, or a combination of

	these techniques.
	■ Have low threshold for aggressive soft tissue coverage.
Positive margins (sarcoma excision)	■ Appropriate preoperative planning is important to minimize risk of unplanned positive margins. ■ Inability to primarily close a wound should not interfere with decision to remove a tumor with a clean margin. Plan on soft tissue reconstruction. ■ Planned positive margins around critical structures such as nerves and vessels may be appropriate in certain settings.

POSTOPERATIVE CARE

- Mobilization and weight bearing depend on the extent of surgery. Activity with no restriction may begin after simple tumor excision, whereas bed rest may be desired after free tissue transfer.
- Extremity elevation is recommended while the patient is in bed.
- May administer antibiotics in the perioperative period.

OUTCOMES

- Oncological outcomes include local recurrence and metastasis. Surveillance for recurrence should be managed by a multidisciplinary sarcoma team. Local recurrence is higher when margins are positive.
- Functional outcomes depend on the extent of tissue resection and patient overall health status. Most patients will experience some form of disability that is proportional to the volume of muscle and bone resected.

COMPLICATIONS

- Local recurrence occurs in a minority of patients with sarcoma and is more common in patients with positive margins.
- Deep infection can occur at any time after surgery and requires aggressive therapy including surgical debridement and antibiotic therapy to achieve limb salvage.
- Weakness with ankle and foot motion is not uncommon given the proximity of the nerves to most leg tumors and the need for extensive muscle excision.

22 Excision of Bone Tumors of the Lower Leg

CHAPTER

Raffi S. Avedian and Rohit Khosla

DEFINITION

- Bone tumors of the tibia and fibula may be benign or malignant (bone sarcoma) and exhibit a variable natural history ranging from latent to rapid growth. Aggressive benign tumors and malignant tumors typically cause pain, dysfunction, and fracture.
- A bone tumor located in the tibia or fibula such that definitive treatment requires excision of an intercalary segment of bone, sparing the ankle and knee joints, is discussed in this chapter.

ANATOMY

- The lower leg is made up of the tibia and fibula and four muscle compartments: anterior, lateral, deep posterior, and superficial posterior (**FIG 1**).
- Three principal arteries travel in the lower leg. The posterior tibial artery is located in the deep posterior compartment on the surface of the tibialis posterior. The anterior tibial artery is in the anterior compartment located deep to the muscles on the surface of the interosseous membrane. The fibular artery travels in the deep posterior compartment medial to the fibula under the flexor hallucis longus; it sends branches to the lateral and anterior compartments and a nutrient vessel to the fibula.
- The deep peroneal nerve travels with the anterior tibial artery. The superficial peroneal nerve is located in the lateral compartment; in the distal one-third of the leg, it travels between the peroneus muscles and extensor digitorum longus and pierces the deep fascia to become a cutaneous nerve.

PATHOGENESIS

- The mechanism for bone tumor formation is not known.
- Risk factors for sarcoma development include radiation exposure, radiotherapy, pesticide exposure, and hereditary conditions including Li-Fraumeni syndrome and retinoblastoma gene mutation.

NATURAL HISTORY

- Active benign tumors such as giant cell tumor of bone, chondroblastoma, and aneurysmal bone cyst will progress over time and may recur after excision but are not lethal.
- All bone sarcomas have the potential for local recurrence and metastasis.
- Some bone sarcomas such as low-grade chondrosarcoma exhibit a slow rate of growth and low risk of metastasis, whereas aggressive tumors like high-grade osteosarcoma and dedifferentiated chondrosarcoma grow rapidly and have a relatively high risk of metastasis.
- Tumor variables that are associated with increased risk of metastasis include high grade and large size (greater than 8 cm).
- Lungs and other osseous sites are the most and second most common location of metastasis, respectively.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pain is a common presenting symptom for aggressive bone tumors.
- A thorough history and examination are important to assess duration of symptoms, comorbidities, physical dysfunction, organ involvement, overall health, and patient expectations to best tailor treatment strategy for the individual patient.
- Neurovascular examination is mandatory for any extremity tumor.

IMAGING

- Plain radiographs are used to formulate a differential diagnosis and a preoperative plan.
- Magnetic resonance imaging is routinely used to determine the extent of intramedullary tumor involvement, presence of soft tissue extension, status of the neurovascular structures, and preoperative planning.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis for a bone tumor includes benign tumors, sarcomas, lymphoma of bone, infection, and metabolic lesions (eg, hyperparathyroidism).

- The most common bone sarcomas are osteosarcoma, chondrosarcoma, and Ewing sarcoma.

FIG 1 • Cross-sectional anatomy of the lower leg showing the contents of the anterior, lateral, superficial posterior, and deep posterior compartments.

SURGICAL MANAGEMENT

- The appropriate treatment for any musculoskeletal tumor is based on its diagnosis and natural history.
- Biopsy incisions are considered contaminated and must be resected at the time of definitive surgery. Care should be taken to place the biopsy in a location that does not interfere with the final surgical plan.
- Intralesional curettage is the preferred treatment for benign tumors. Radical resection with a clean margin is required for bone sarcomas.
- Reconstruction depends on the extent of bone excision and may include simple bone grafting, endoprosthetic implants, structural allografts, vascularized fibula (ipsilateral centralized or contralateral free transplant), or combined allograft and vascularized fibula.

- The goal of surgery is to remove the tumor adequately to minimize recurrence and restore the mechanical integrity of the bone and joints so that the patient may have sufficient function to perform activities of daily living with minimal pain.

Preoperative Planning

- A patient is considered ready for surgery after completion of staging and multidisciplinary review of pertinent imaging, pathology, and treatment strategy.
- The surgical plan is created by thorough study of the preoperative radiographs and MR imaging.
- Bone cuts are planned by measuring on preoperative imaging the distance from an intraoperatively identifiable landmark (eg, medial malleolus or tibial condyle) to the desired osteotomy site (**FIG 2A,B**).
- The soft tissue margin depends on the size and location of a soft tissue component to the tumor.
- When tumor abuts, but does not encase blood vessels or nerves, they can be dissected free by leaving the adventitia and epineurium on the tumor as the margin.

FIG 2 • A. Anteroposterior radiograph of a 16-year-old girl with a midtibia Ewing sarcoma. **B.** Sagittal T1-weighted MRI demonstrating the intramedullary extent of the tumor and measurements for bone resection.

Positioning

- Patient positioning is based on the surgeon's assessment of the critical anatomy of the surgery and how best to visualize it during surgery.
- Supine is the most common position for tumor excision of the lower leg. A hip bump may be used to access more lateral tumors; conversely, frog legging the extremity facilitates medial and posterior visualization.
- If a flap is to be used, the harvest must be performed using a separate back table and instruments and the surgical sites completely isolated to avoid contamination.

Approach

- The surgical approach varies based on location of the tumor.
- Previous biopsy and surgical scars are considered contaminated and must be excised en bloc with the tumor.

TECHNIQUES

■ Diaphyseal Tibia Tumor Resection and Reconstruction

- Tourniquet is used at discretion of the surgeon by using gravity exsanguination rather than Esmarch to avoid tumor dissemination.
- A longitudinal incision is created that ellipses out the biopsy site. Skin flaps are created as needed to ensure adequate visualization of the tumor and critical anatomy (**TECH FIG 1A,B**).
- Soft tissue dissection around the tumor is performed with the following principles:
 - Adequate visualization must be achieved.
 - Margin of healthy tissue is kept on the tumor.
 - Nerves must be moved away from tumor. The epineurium may be used as margin if tumor abuts the nerve.
 - Vessels must be moved away from tumor; the adventitia may be used as margin if tumor abuts the vessels.
 - Single-vessel runoff to the foot may be acceptable depending on the extent of soft tissue and collateral circulation excision.
- Bone cuts are performed based on preoperative planning and measurements

to ensure complete tumor removal. Steinman pins may be inserted proximal and distal to bone cuts prior to osteotomy for the purpose creating reference points for leg length and rotation restoration (**TECH FIG 1C,D**).

- Alternatively, an external fixator may be applied prior to osteotomy to facilitate leg length and rotation restoration.
- Fluoroscopy may be used at the discretion of the surgeon.
- Hemicortical resection is an option if the tumor does not involve the entire diameter of the bone.
- Reconstruction is performed to restore mechanical stability of the extremity using one of the following options:
 - Endoprosthetic implants may be cemented or press fit into native bone.¹
 - Allografts are fashioned to fit the defect and secured in place with internal fixation.
 - Vascularized fibula may be inserted end-to-end to the native tibia or telescoped into the tibial canal to increase contact surface area (**TECH FIG 2A–C**).
 - A composite graft using vascularized fibula inserted into a structure allograft (Capanna technique) has the theoretical advantage of combining the structural support of a large allograft with the healing potential of a vascularized graft.²
 - Ilizarov technique for bone lengthening.³
- Allografts and endoprosthesis are at increased risk for infection; thus, aggressive soft tissue reconstruction is recommended to minimize risk of wound dehiscence resulting in exposed hardware.
- Often, primary closure is not possible, and a local rotational flap or free tissue transfer is used to reconstruct the soft tissues.

TECH FIG 1 • A. Intraoperative photograph of planned incision incorporating biopsy site. **B.** Dissection through skin and elevation of full-thickness flaps to visualize the extent of tumor. Steinmann pins are placed proximal and distal away from tumor as references for leg length and rotation. **C.** Bone cuts are made and muscle attachments released to allow excision of the tumor in its entirety. **D.** The ipsilateral fibula is dissected free keeping the flexor hallucis longus muscle and associated nutrient vessels attached. Notice that additional fibula length relative to defect is harvested to allow for intramedullary insertion.

TECH FIG 2 • A. Photograph showing fibula inserted into the proximal and distal ends of the tibia. **B.** The fibula is stabilized to the native tibia with internal fixation, and allograft strut is placed for additional support. **C.** Radiograph 14 months after surgery showing incorporation of the fibula and allograft to the native tibia.

PEARLS AND PITFALLS

Wound breakdown

- Dead space after tumor removal should be managed with drains, muscle flap, free tissue transfer, or a combination of these techniques.
- Have low threshold for aggressive soft tissue coverage.

Positive margins

- Appropriate preoperative planning is important to minimize risk of unplanned positive margins.
- Planned positive margins around critical structures such as nerves and vessels may be appropriate in certain settings

Allograft nonunion/fracture

- May be minimized by good cortical apposition of graft to the native bone.
- Restrict weight bearing until evidence of bone healing is observed.
- Counsel patients that reoperation for nonunion is possible.

Malrotation/malalignment

- Provisional placement of internal fixation, reference pins, or external fixation away from tumor may be used to maintain anatomic alignment.

POSTOPERATIVE CARE

- Mobilization and weight bearing depend on the extent of surgery.
- Extremity elevation is recommended while the patient is in bed.
- Range of motion and therapy may begin after wound healing is sufficient.

- May administer antibiotics while drains are in place.

OUTCOMES

- Oncological outcomes include local recurrence and metastasis. Surveillance for recurrence should be managed by a multidisciplinary sarcoma team. Local recurrence is higher when margins are positive.
- Functional outcomes depend on the extent of tissue resection and patient overall health status. Most patients will experience some form of disability that is proportional to the volume of muscle and bone resected.
- Benevenia et al. showed an overall 27% nononcological complication rate for intercalary prosthesis and average 77% Musculoskeletal Tumor Society function score.⁴

COMPLICATIONS

- Allograft nonunion and fracture, endoprosthesis loosening, and infection are known complications and typically require additional surgery to achieve a limb salvage.
- Local recurrence occurs in a minority of patients and is more common in patients with positive margins.
- Malalignment of the reconstruction may occur and can be avoided by the use of provisional fixation prior to making bone cuts and intraoperative radiographs to ensure restoration of alignment and rotation.
- Deep infection can occur at any time after surgery and requires aggressive therapy including surgical debridement and antibiotic therapy to achieve limb salvage. Removal of implants and allografts is often necessary to eradicate infection.

23 Debridement of Soft Tissue Infections of the Lower Leg

CHAPTER

L. Scott Levin Paul Magnuson, and Paulo Piccolo

DEFINITION

- The term *debridement* was coined by Joseph Pierre DeSault in the 18th century. The French term implies the removal of soft tissues and bone that are nonviable, with the goal of preventing infection. It is defined by the Oxford medical dictionary as the process of cleaning an open wound by removal of foreign material and nonviable tissue, so that healing may occur without hindrance.¹
- By removing molecular, physical, and microbiologic barriers to healing, debridement facilitates endogenous wound healing.

ANATOMY

- The lower extremity consists of four major regions: the hip, thigh, leg, and foot. It is specialized for support of body weight, adaptation to gravity, and locomotion.
- The thigh is divided in three compartments (anterior, posterior, and medial), and the leg is divided in four compartments (anterior, deep, superficial posterior, and lateral).

PATHOGENESIS

- Wounds may originate through a variety of causes, such as soft tissue infection (acute or chronic), trauma (thermal, electric, chemical, penetrating, or blunt), vascular issues (arterial, venous, or lymphatic), neuropathic (eg, diabetes), or malignancy.
- The pathogenesis of the wound will play a key role in the treatment plan. A wound from necrotizing fasciitis needs emergent attention and wide

debridement, as opposed to one caused by venous stasis, which can be dealt with in an ambulatory setting and may be amenable to a more conservative treatment approach.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history of present illness must be obtained. This is paramount in establishing the cause, timing, and clinical implications of that wound, the potential level of disability caused by it, and to plan further treatment.
- Patient's comorbidities such as obesity, diabetes, peripheral vascular disease, surgical history, nutritional status, previous trauma and, nicotine use should all be taken into account.
- A thorough physical exam of the extremity in question must be performed preoperatively, and many times, it should be completed in the operating room under anesthesia to minimize patient's discomfort and allow for a precise and thorough analysis of the area.
- Nerve integrity must be assessed before the patient is under anesthesia—both motor and sensory aspects must be checked from the proximal thigh to the distal toe.
- Peripheral pulses are of extreme importance when treating lower extremity wounds, as this will give vital information regarding limb perfusion, wound pathogenesis, and options for future reconstruction.
- Size and appearance of the wound, characteristics of the surrounding soft tissue, and skeletal stability of the extremity should also not be overlooked. The presence of exposed vital structures, including nerves, vessels, bones, and joints, must be appreciated and well documented on the patient's chart. The presence of foreign body on the wound bed must be ruled out (eg, a chronic wound caused by a retained piece of packing/dressing material).

IMAGING

- Preoperative imaging studies are not always mandatory but often provide valuable information to the reconstructive surgeon.
- Plain films are important to assess proper bony alignment in the setting of trauma or in acute infections to quickly assess for the presence of subcutaneous gas.
- Computed tomography (CT) with the aid of intravenous contrast (computed tomography angiography [CTA]) may determine proper vascularization to the extremity when there is any question regarding distal blood flow, be that acute

or chronic.

- Bone scans and magnetic resonance imaging (MRI) to assess for bone viability or osteomyelitis are important adjuncts when planning for debridement of a lower extremity wound with exposed bone.
- Other imaging modalities may aid the operating surgeon in evaluating vascularity of the bone such as PET scans.²

SURGICAL MANAGEMENT

- The decision to perform a surgical debridement of a lower extremity wound lies in the hands of the reconstructive surgeon.
- Before the era of free tissue transfer, debridement was often limited because removing questionable tissue could lead to exposure of vital structures, such as tendon devoid of paratenon, vessels, or nerves, and bone devoid of the periosteum. Surgeons were reluctant to make the traumatic defects larger by radical debridement. Subsequently, surgical techniques were more conservative, and healing by secondary intention with wound contracture, scar, and unstable soft tissues was the rule. Currently, free tissue transfer using large well-perfused flaps facilitates radical debridement and necrectomy (removal of dead tissue).

Preoperative Planning

- General anesthesia is preferred. If patient is not a suitable candidate for general anesthesia due to comorbidities, spinal anesthesia or regional block can be considered.

FIG 1 • Left lower extremity wound following high-energy trauma resulting in severe wound involving soft

tissue and bone. An external fixator was necessary for skeletal support due to severe bony comminution.

- As mentioned previously, a more thorough physical exam can be performed with the patient under anesthesia.
- Debridement should be performed with the use of the tourniquet. The tourniquet is inflated to 350 mm Hg after an Esmarch bandage is used to exsanguinate the limb. In cases of malignancy or infection, the use of the tourniquet is contraindicated. In these cases, elevating the leg for 5 minutes before inflating the tourniquet aids in limb exsanguination.
- In an ischemic operative field, it is simpler to distinguish between healthy and damaged tissues. The basic elements of this judgment are the appearance and consistency of the tissues. Healthy tissue in the exsanguinated field is bright and homogeneous in color. Subcutaneous tissue is yellow, muscles are bright red, and the tendons and fascia have a white and shiny appearance.
- Damaged tissues are recognized by the presence of foreign bodies, irregular tissue consistency, and irregular distribution of dark red stains, caused by hematomas or hemosiderin (**FIG 1**).
- Evaluating muscle viability may propose a challenge in some cases. Classically, the so-called 4 Cs—muscle color, consistency, contractility, and capacity to bleed—are generally used to assess muscle viability and guide debridement. Recent studies, however, show a potential tendency for normal muscle resection³ as the surgeon's impression of muscle viability does not correlate with histological findings of the debrided muscle in the majority of cases. Therefore, when large amounts of muscle appear of questionable viability in the first stage of debridement, a second trip to the operating room may be necessary to avoid over resection of viable muscle. This is in contrast with clearly necrotic muscle, which will be discussed further.
- Chronic wound
 - A: Chronic wounds present a different challenge to the surgeon. The presence of scarring in the wound bed may impair the surgeon's ability to appreciate important aspects of the wound such as occult infection, its true area and depth, and potential undermining and tunneling (**FIG 2**).
 - B: Due to the fact that these wounds remain open for a prolonged period of time, in addition to other factors such as poor blood flow and hypoxia, they are prone to become heavily colonized with bacterial or fungal organisms,

leading to biofilm formation (glycocalyx).

FIG 2 • Chronic right posterior ankle wound. One can appreciate the surrounding scarring and the exposed Achilles tendon with marked desiccation from prolonged exposure. Undermining may not be immediately appreciated, but further debridement may demonstrate tissue undermining and small pockets of fluid and nonviable tissue.

Positioning

- The patient is positioned supine on the operating room table.

Approach

- A “top-down” or “outside-in” approach to the debridement should be undertaken, starting with the skin and subcutaneous tissue, followed by the fascia and muscle, neurovascular structures, and bone.

TECHNIQUES

■ Sharp Debridement of the Acute Wound

- The patient is prepped with antiseptic solution and draped. The extremity is elevated (as described above), and the tourniquet is inflated to 350 mm Hg.
- Next, the wound is superficially washed gently with irrigating solution

usually attached to a cystoscopy tubing or through a bulb syringe to eliminate blood clots or superficial debris. Pulsed irrigation systems are advocated by some, but if used too vigorously with too high pressure or too close to tissue planes, particularly around tendons, nerves, and vessels, it can insufflate fascial planes, causing excessive tissue damage and increased edema. Furthermore, it may not be productive in removing bacterial contamination.⁴

- First, a no. 10 or no. 15 scalpel or sharp scissors are used to excise the skin and dermis, particularly around the edge of the wound, back to the normal tissue.
- Next, the subcutaneous layer is inspected, debrided sharply with a no. 10 or no. 15 scalpel to the level of the fascia. All fascia that is ripped, avulsed, or contaminated is then removed.
- The next layer encountered is the muscle. Necrotic muscle should be excised and removed from the wound bed regardless of the volume. Leaving unhealthy, necrotic muscle is most likely to result in subsequent infection. This is often difficult to assess in a crush injury or gunshot blasts where the zone of injury is less clearly defined (**TECH FIG 1**).
- Denuded tendon, if not frayed, should be cleaned or fixed with a suture to the surrounding tissue for later reconstruction.
- Severed vessels are ligated, provided they are of no significance in the viability of the injured extremity. If vessels are vital, they are excised to normal-looking margins, and continuity is restored with interposition vein grafts.

TECH FIG 1 • Left lower extremity wound caused by a gunshot resulting in severe soft tissue and bony

trauma. There is a large amount of injured muscle evidenced by the dark red stains, in contrast with likely viable muscle superiorly.

- The nerves are the only structures in which debridement is not radical. Those parts that are destroyed without any doubt are removed, and nerve stumps are tagged and anchored in the wound so as to avoid traction and allow later reconstruction with nerve grafts. We prefer that a large cystoclip or hemoclip be applied to the nerve stump so this can be seen on radiograph and appropriate secondary planning can be done in terms of surgical approach and location of the neuroma stump.
- The periosteum that is elevated from the bone should be excised to the level from which it is elevated. Small bone fragments devoid of the periosteum or free-floating large segments, although they may be of structural significance, should be removed for fear of colonization, contamination, and latent infection.
- At the conclusion of debridement, the wound is again irrigated and tourniquet is let down, and then all tissue planes, particularly muscle, are observed for bleeding as the arterial pressure increases in the limb.
- Areas that are persistently nonviable, particularly the dermis, skin, and muscle, are excised. Excision then can be done sequentially, watching for punctate bleeding from either the dermis or the muscle. If large flaps have been avulsed, excision is carried out through the skin to the level of bright red blood coming from dermis on incision.
- No attempt should be made to close the wound defect under any undue tension for fear of further ischemic damage to already compromised tissues.
- In cases of degloving injuries, the sequence of debridement remains the same; however, in the end of the procedure, the portions of the avulsed skin that appear viable may be used as a full-thickness graft after thorough in situ defatting with sharp scissors or blade and bolstered to the wound. Special attention is warranted in the postoperative period to ascertain skin graft take.⁵
- Avulsed flaps with impaired venous outflow may be salvaged with microsurgical venous anastomosis to more proximal veins.

■ Debridement of the Chronic Wound

- Debridement of a chronic wound is also done with the limb exsanguinated with aid of a tourniquet.
- Superficial scar is excised completely so that the wound margins are in healthy skin and subcutaneous tissue appears normal. The goals are to treat the chronic wound like a tumor and excise it in its entirety down to normal tissue planes. All scar in the wound should be removed in the same manner as tumor surgeons operate; that is, the knife should always cut through healthy tissues.
- If a sinus tract is present or suspected, methylene blue dye may be injected to identify its limits and its course. This way the entirety of the sinus tract can be excised to its origin.
- If functionally important structures are entrapped in the scar, the dissection should commence in the healthy surrounding tissue, passing toward the scar entrapment, where the structures such as nerves or tendons are carefully dissected.
- All areas of the bone not covered with the periosteum are removed, and those that are exposed are burred with an iced saline bur. If punctate bleeding is encountered from the cortical bone, the bone is left behind. If not, the bone is removed until the so-called paprika sign, is identified. This is punctate bleeding from the Haversian canals and indicates bone viability.
- If there is sequestrum in the medullary canal, the anterior part of the bone cortex, such as in the anterior tibia, should be removed even if it is well perfused, to allow access to the medullary canal for placement of muscle flaps that eliminate dead space and help control infection.

■ Hydrosurgery System

- Recently, new modalities for wound debridement have emerged such as the use of hydrosurgery systems (VERSAJET, Smith & Nephew, London, UK). This novel modality allows accurate debridement of only unwanted tissue while precisely conserving viable structures for eventual repair. It employs a high-pressure water jet at 15 000 psi to create a Venturi effect, which eliminates debrided tissues in the water stream, extricating it from the underlying tissue (**TECH FIG 2**).⁶
- The cost-effectiveness of such systems is still controversial, and it may not be superior to conventional debridement so its use is left up to the surgeon's

preference and the capabilities of the facility in which he/she operates.

TECH FIG 2 • VERSAJET system for wound debridement.

■ Other Forms of Wound Debridement

- Many other forms and mechanisms for debridement have been described but are beyond the scope of this chapter such as biodebridement using maggots, enzymatic debridement using topical products such as collagenase, newer technologies such as ultrasound therapy, and plasma-mediated bipolar radiofrequency ablation.⁷
- These methods are measured against the current reference standard, which is the sharp debridement technique described, and the method of choice for a particular wound depends on various factors such as type, size and position of wound, quantity and character of the exudate, patient tolerance, cost-effectiveness and available equipment, and expertise of the treatment team.

PEARLS AND PITFALLS

Use of tourniquet

- The use of tourniquet decreases the amount of blood loss during the procedure.
- The use of Esmarch bandage is not necessary and sometimes discouraged (eg, presence of infection or malignancy) as elevating

	the extremity for approximately 5 minutes should exsanguinate the extremity satisfactorily.
Hemostasis	■ Thorough hemostasis is performed after tourniquet is let down and arterial pressure rises.
Necrotic muscle	■ Muscle that appears clearly necrotic should be excised. Leaving necrotic muscle behind is the surest way to acquire an infection.
Loupe magnification	■ Use of loupe magnification helps the operating surgeon better identify structures during the debridement. It also aids in differentiating between viable and nonviable tissues.
Technique	■ The surgeon should approach the debridement as one would a tumor, ie, excise its entirety down to healthy tissue.

POSTOPERATIVE CARE

- An occlusive dressing is applied according to the surgeon's preference. Dressing changes should be performed on a daily or every-other-day basis.
- Patient's comfort is of paramount importance, so proper postoperative pain control should be optimized and depending on size and location of the wound; dressing changes have to be performed in the operating room under sedation or general anesthesia.
- Wound surfaces must be continually moistened and tissue desiccation must be prevented.
- The use of splints may aid in postoperative comfort and should be considered for the postoperative period.
- Elevation of the limb is of utmost importance to decrease the amount of edema and aid in limb circulation.
- Finally, one should take care of the “whole patient, not the hole in the patient”—proper medical optimization, nutrition assessment, and physical rehabilitation must be arranged as part of the postoperative regimen.

OUTCOMES

- The primary outcome is wound healing. This may not be achieved by debridement and closure alone.
- Depending on the size and etiology of the wound, further treatment may be warranted. Frequent dressing changes, application of biomaterials, or coverage with a skin graft or flap may be necessary and are used at the discretion of the treatment team.

COMPLICATIONS

- Nonhealing wound. This may be caused by inadequate debridement of necrotic tissues or foreign bodies, persistent contamination, underlying metabolic disorder, noncompliance with postoperative care, or any other number of factors.
- Secondary infections. This is caused mainly by failure to debride necrotic tissue or to remove colonized foreign body from the wound bed, which serves as substrate for microorganism superinfection.

DEFINITION

- Trauma and neoplasia, requiring segmental bone resection, are the most common causes for segmental defects of the tibia.
- Radiation-induced bone necrosis and infection, namely osteomyelitis, is also an indication for resection and possible reconstruction.
- Reconstruction requires technical expertise, careful operative planning, and a detailed understanding of the problem at hand.
- Large commitment by both the patient and the physician is paramount due to long complex rehabilitation period.
- Options for reconstruction include either allograft or autograft material, most commonly a vascularized fibular graft.
- Allografts were initially used but were associated with considerably high rates of complications and failures.
- The concept of reconstruction of the tibial shaft with a vascularized fibular graft was first suggested by Chacha and colleagues in 1981.¹ They used the ipsilateral fibula as a vascularized pedicle graft for nonunion of the tibia.
- It has since been shown to be a viable and reliable technique for tibial reconstruction.
- The main advantage of using a vascularized autograft for tibial reconstruction is the ability to use the normal biology of bone healing for incorporation rather than relying on creeping substitution innate to prosthetic material/nonvascularized graft use.
- The vascularized fibular graft undergoes hypertrophy overtime in response to continuous pressure load, which translates to remarkable long-term

durability.²⁻⁴

- Factors that make the fibula an optimal source for a vascular graft are as follows:

- Anatomic accessibility
- Independent blood supply
- Relatively dispensable in lower extremity function
- Capability to hypertrophy overtime in response to pressure

ANATOMY

- The tibia is the second largest bone in the human body, after the femur.
- Relevant leg anatomy includes four compartments (anterior, posterior, superficial, and deep posterior) (**FIG 1**).
- The tibia is the stronger of the two bones in the lower leg. It is found on the medial side and is connected to the fibula by the interosseous membrane. It forms a type of fibrous joint called syndesmosis with very little movement.

FIG 1 • Cross-sectional anatomy of four compartments at the midtibial level.

- The blood supply to the tibia is derived from a main nutrient artery and periosteal branches derived from the anterior tibial artery.

- The fibula is a long and thin cortical bone with a small medullary component. In adults, the width of the fibula is 1.5 to 2 cm with a length of 35 cm of which approximately 25 cm of the fibular diaphysis can be harvested for free grafting.
- Vascular supply to the diaphysis of the fibula is via a dominant nutrient endosteal artery and minor musculoperiosteal branches from the peroneal artery and veins. These vessels run parallel to the fibula and course between the flexor hallucis longus (FHL) and tibialis posterior muscle group.
- The dominant nutrient artery branches 6 to 14 cm from the peroneal artery bifurcation and enters the fibula posterior to the interosseous membrane. It then courses into the nutrient foramen located in the middle third of the diaphysis and further divides into an ascending and descending branch.
- Musculoperiosteal vessels are derived from the peroneal artery and travel within the posterolateral septum, through the flexor hallucis longus and tibialis posterior muscle, giving segmental rise to four to eight branches that supply the muscles in the anterior compartment, soleus muscle, and lateral leg skin territory. The majority of the periosteal branches are located in the middle third of the fibula.
- Soft tissue defect coverage is achieved with a skin paddle supplied by perforators traversing through the posterior crural septum with the majority concentrating at the proximal and distal ends of the fibula. These fasciocutaneous perforators supply a skin paddle up to 10 × 20 cm in size.⁵

PATIENT HISTORY AND PHYSICAL FINDINGS

- Detailed preoperative evaluation is required for patients undergoing extensive long bone resection and intercalary bone defect reconstruction.
- Determination should first be made as to whether reconstruction or salvage is a viable option.
- General health status should be carefully evaluated. An extensive reconstructive effort should not be undertaken on a patient with an overall poor health status.
- The patient should have the ability to be compliant with both treatment and rehabilitation.
- Pertinent history includes the presence of significant comorbidities such as deep venous thrombosis, peripheral vascular disease, lymphedema, trauma, venous insufficiency, diabetes, or social history such as smoking.
- Special attention should be to consider cardiovascular, surgical, or hematologic diseases that may affect peripheral blood flow.

- Physical exam should include a lower extremity and vascular examination. This includes an evaluation of knee and ankle joints for range of motion and laxity and a foot Allen test with a Doppler probe to assess dorsalis pedis and posterior tibial arteries.
- Peronea arteria magna is a congenital variant of the arterial inflow to the foot that affects about 1% to 8% of the population, where both the anterior and posterior tibial arteries are hypoplastic or absent with the peroneal artery serving as the single arterial supply below the knee. The artery may need to be reconstructed with a vein graft, or the other leg should be inspected.
- Patients with an abnormal vascular exam or a history of trauma to the affected extremity will need additional preoperative imaging such as computed tomography angiogram (CTA), duplex ultrasound, or magnetic resonance angiography (MRA) to identify atherosclerotic occlusive disease or congenital anomalies.

IMAGING

- Preoperative imaging of both the recipient and donor sites should include an evaluation of:
 - Recipient site:
 - The extent of bone resection, length and diameter of the intercalary defect, and potential soft tissue defect (**FIG 2**). This allows the surgeon to determine the extent of the tumor burden, traumatic bone loss, or chronic osteomyelitis and plan for reconstructive options.
 - Donor site:
 - Evaluate vascular supply with Doppler ultrasound (anterior tibial, posterior tibial, and dorsalis pedis arteries), and exclude any fibular deformities.
 - Angiogram to look for vessel patency and flow to the foot

SURGICAL MANAGEMENT

Preoperative Planning

- Determination must be made as to whether limb salvage is a viable option.
- Taking into account patient factors and the extent of disease and/or resection is imperative in determining the need for tibial reconstruction vs amputation.
- Assessment of defect must include the need for bone, muscle, and skin; all of which free fibular graft can provide.
- Four centimeters of bone must be left proximally, whereas 6 cm must be left at

the distal portions of the fibula for knee and ankle stabilization, respectively. Therefore, the maximum length of the graft obtainable will be the length of the donor tibia less 10 cm.

- Donor site should be the contralateral leg if used as a free flap. This allows for simultaneous preparation of recipient site during fibula harvest and avoids the use of potentially injured/involved donor site where the fibula may have been fractured in the setting of trauma.

Positioning

- Positioning depends mainly on the recipient site, as the fibula can be harvested in both supine and lateral positions.
- For contralateral free fibula flap harvest, the proper positioning facilitates two teams to work together for recipient preparation and donor dissection simultaneously (**FIG 3**).
- In a supine position, a roll is placed under the ipsilateral hip, and the patient's knee is bent to 90 degrees.

FIG 2 • Preoperative MRI showing left proximal tibial osteosarcoma.

- A heel stop can be placed on the operative room table to help knee at 90 degrees when harvesting in the supine position.
- If the patient is in a prone position, a roll is placed under the anterior ipsilateral hip, and bending of the leg is not required.
- All pressure points should be carefully padded and protected.

FIG 3 • If the contralateral fibula flap is desired, the patient can be placed in a supine position, which allows two teams to work simultaneously for recipient preparation and donor site harvest.

Approach

- Multidisciplinary team approach is taken involving both plastic surgeons and orthopedic surgical teams to coordinate resection of the involved tibial bone and reconstruction of the ensuing intercalary defect.
- Careful planning of the incision for the exposure is necessary for flap harvest and inset without compromising the skin envelope for coverage.
- Tibial reconstruction can be achieved with free or pedicled fibula graft, in a single- or double-barrelled fashion.
- Reconstruction of smaller intercalary defects up to 13 cm can be achieved with double-barrelled fibular flap, keeping the arterial blood supply intact while performing an osteotomy in the fibula flap.
- If a pedicled flap is desired, the ipsilateral leg will be used for both harvest and

inset. The advantages of pedicled flaps are that microvascular anastomosis is unnecessary, and distant donor-site morbidity is avoided, which can occur with free fibula graft.⁶

- Intraoperative preparation of the fibula flap includes marking of anatomical landmarks: head of the fibula, lateral malleolus, and anterior and posterior fibular border (**FIG 4**).
- If a skin deficit is present either in the setting of tumor/chronic osteomyelitis resection or trauma, a skin paddle can be harvested with the fibular flap sharing the same vascular pedicle, which facilitates early detection of flap compromise and provides tension-free skin closure of recipient site.
- A perforator is marked on the proposed skin paddle using intraoperative Doppler localization along the posterior border of the fibula, corresponding to the posterior intramuscular septum.

FIG 4 • Intraoperative marking of anatomical landmarks for a contralateral fibula harvest: head of the fibula, lateral malleolus, anteroposterior fibular border, and skin paddle if needed.

TECHNIQUES

■ Free Fibula Flap

- After the tibial bone resection is completed by the orthopedic surgical team, the dimensions of the intercalary bone defect are measured (**TECH FIG 1A**).

- Prior to flap harvest, a sterile tourniquet is placed on the midthigh while avoiding compression over the fibular head and common peroneal nerve.
- Using marked anatomical landmarks, a midlateral vertical incision is made over the fibula, and skin flaps are elevated at the level of the fascia.
- Dissection is carried through the investing fascia of the lateral compartment, anterior to the posterior intermuscular septum (**TECH FIG 1B–D**).
 - Care should be taken to preserve fasciocutaneous perforators traveling through the posterior intermuscular septum if a skin island is needed for osteocutaneous flap.
- During proximal dissection, identify and preserve the common peroneal nerve traversing around the head of the fibula to become the superficial peroneal nerve.
- The peroneal muscles are dissected off the anterior surface of the fibula and reflected anteriorly to expose the anterior intermuscular septum. After incising the septum to gain access to the anterior compartment, reflect the extensor digitorum and hallucis muscles to identify and preserve anterior tibial vessels and deep peroneal nerve.
- The interosseous membrane is incised to enter the deep posterior compartment, and the peroneal vessels are located between tibialis posterior and flexor hallucis longus muscles.
- Next, the peroneal vessels are identified proximally and distally, and dissection is propagated circumferentially around the fibula and staying medial to the vessels using a large right angle clamp. The vascular pedicle should be maintained during dissection.
- After adequate length of the fibula is marked for reconstruction, towel clamps are used to apply lateral traction on the proximal and distal fibula while osteotomizing with an oscillating saw or Gigli saw. A strip of periosteum overlying the osteotomy site should be included to overlap the osteotomy sites at the recipient site.
- Prior to performing osteotomy, a microvascular clamp can be applied to the peroneal artery distal to the osteotomy site to ensure adequate supply to the foot and then divided (**TECH FIG 1E**).

TECH FIG 1 • A. Intraoperative photograph of the left intercalary defect remaining after the tumor resection. **B.** Exposure of peroneus longus and soleus at the midtibial level. **C.** Dissection around the fibula and lateral muscle compartment. Proceed dissection proximally to identify and protect the superficial peroneal nerve. **D.** Dissection proceeds anterior to the fibula through the anterior intermuscular septum and protects the deep peroneal nerve and anterior tibial vessels. **E.** After the distal fibula osteotomy, the peroneal vessels should be ligated distally, which are

located between FHL and tibialis posterior muscle groups. **F.** Adequate fibula length is freed, and proximal osteotomy is performed carefully while protecting the pedicle vessels.

- The vascular pedicle is dissected starting distally, carried proximally up to the origin of tibioperoneal trunk, and ligated with approximately 2 to 6 cm of pedicle length.
- After the fibula graft is fully mobilized with the pedicle (**TECH FIG 1F**), the tourniquet is released with robust arterial inflow and venous outflow and healthy back bleeding from both the periosteum and intramedullary canal.
- An osteomuscular flap can also be harvested in similar fashion to include soleus and flexor hallucis longus muscles. This can aid in filling the dead space in patients with extensive soft tissue defect.
- If the distal osteotomy is close to the lateral malleolus, a screw fixation to the tibia can be utilized to prevent valgus deformity and ankle instability, which is more important in pedicle flap.
- In a clean and well-vascularized recipient bed, the proximal and distal tibial should be stabilized, and the medullary cavities should be prepared to receive the free fibula graft.
- The free fibula graft is then telescoped into the intercalary defect. Next, the graft is anchored to the tibia proximally and distally with long compression plates and screws spanning the bone defect. During this step, care is taken to prevent any damage to the peroneal vessels.
- Standard microvascular anastomosis is performed between the recipient vessels and peroneal artery and accompanying venae comitantes. Additionally, several fat grafts can be placed around the pedicle in an effort to prevent compression.
- After skin closure, a well-padded posterior leg splint is applied to keep the foot in extension to prevent an equinus deformity.

■ Pedicled Fibula Graft

- The recipient site defect is measured to estimate the length of the fibula required for reconstruction (see **TECH FIG 1A**).

- If the fibula flap is to remain pedicled (**TECH FIG 2A**), the flap is raised in standard fashion, but the proximal vascular pedicle is not ligated (**TECH FIG 2B**).
- The vascularized fibula flap is then transported through the space created between the tibialis posterior muscle and the tibialis anterior muscle.
- The distal-most segment of the bone will be used for the reconstruction. It can either be transposed or reversed, but whichever way the flap is oriented, it needs adequate pedicle length.
- If the fibula is reversed and rotated 180 degrees, the pedicle will make a U-turn, and care needs to be taken not to kink the pedicle on inset.

TECH FIG 2 • A. Illustration of pedicled fibula graft with intact peroneal vessels. **B.** Intraoperative photograph of an ipsilateral pedicled fibula graft. **C.** Intraoperative photograph showing an allograft spanning the defect and an onlay fibula graft being stabilized with long compression plates and screws.

- Additionally, if the length of the vascular pedicle of the graft is expected to be inadequate, it is necessary to harvest the graft as far from the base of the pedicle as possible and separate the periosteum with the vascular pedicle to make a longer vascular pedicle.
 - Once inset as an interposition graft, bone fixation of the fibula graft is achieved with long compression plates and screws traversing the tibial defect.
 - Alternatively, an allograft can be used as an interposition graft spanning the intercalary defect with an onlay fibula graft as a buttress, which can provide greater stability (**TECH FIG 2C**).
-

■ Double-Barrelled Fibula Technique

- Blood supply to the fibula is both endosteal and periosteal.
- This technique is useful for proximal tibial reconstruction when the defect is shorter than 13 cm.
 - Larger defects will not be able to be reconstructed with a single fibula in a double-barrelled fashion; both fibulas would be required, and the second fibula would need to be as a free fibula flap.
 - Additionally, this method provides two segments of bone, which doubles the cross-sectional area of the flap but only requires one anastomosis.
- Following the harvest, the graft is osteotomized at the midpoint, taking care to avoid the peroneal vessels (**TECH FIG 3**).
- At the site of the proposed osteotomy, the vascular pedicle is carefully elevated off the bone flap in the subperiosteal plane with an elevator over a segment of 2 to 3 cm, which will allow a malleable retractor to be placed to protect the pedicle.
- The graft is osteotomized at the midpoint and folded, with care taken to preserve the peroneal vessels.

TECH FIG 3 • In the double-barrelled fibula repair, free fibula is harvested with the peroneal vessels intact. The graft is then osteotomized at the midpoint and folded.

PEARLS AND PITFALLS

Peronea arteria magna

- A congenital variant of the arterial inflow to the foot, where both the anterior and posterior tibial arteries are hypoplastic or absent with the peroneal artery serving as the single arterial supply below the knee.

Injury to common peroneal nerve

- The nerve courses inferior to the head of the fibula and should be identified during proximal dissection to prevent injury.

Careful dissection

- Preserve the posterior intermuscular septum, which carries perforators to the skin paddle.

of skin perforators

Joint instability

- At least 4 cm of fibula bone is preserved proximally to preserve the stability of the knee.
- At least 6 cm of fibula bone is preserved distally above lateral malleolus to preserve stability of the ankle.

POSTOPERATIVE CARE

- Recipient and donor sites should be monitored during the postoperative period for vascular insufficiency and signs of free flap compromise, which can be monitored if a skin island is harvested.
- Flap function can be monitored with a combination of clinical exam and a Doppler probe every hour during the first 24 hours. The flap patency should be assessed until patient discharge.
- Initially, patients should be advised no weight bearing on the surgical limb up to 2 weeks. Afterward, partial weight bearing can be resumed with assistance and progressed to full weight-bearing status after bone union.

OUTCOMES

- Union time can range from 3 to 7 months.
- Union rates upward of 75%.
- Ambulation: all patients (100%) at an average 9.5⁵ to 14.3 months⁷.
- Joint stiffness (40%) and pain (18%) are frequent⁸.
- Fibular hypertrophy occurs secondary to microfractures and callous formation.

COMPLICATIONS

- Recipient site
 - Loss of flap primarily caused by vascular thrombosis
 - Nonunion
 - Infection
 - Hardware malfunction
- Donor site
 - Inability to flex the great toe due to damage to flexor hallucis longus:
 - Knee or ankle joint instability with secondary pseudoarthrosis
 - Common peroneal nerve injury

ACKNOWLEDGMENTS

Thank you to Drs. C. Arroyo-Alonso and A.J. Steinberg, Institute for Reconstructive Surgery, Houston Methodist Hospital and Weill Cornell Medicine, Houston, Texas, for their contributions to the preparation of this chapter.

25 Soft Tissue Coverage of Lower Leg—Free Flap

CHAPTER

Goo-Hyun Mun and Kyong-Je Woo

DEFINITION

- Microvascular free flap transfer is a reliable and often ideal option for soft tissue reconstruction of a complex or large wound of the lower leg.
- The goal of reconstruction is to provide durable soft tissue coverage to maximize bony union in a traumatic wound and functional recovery and to restore the aesthetic contour of the lower leg.

ANATOMY

- Three main arteries branching from the popliteal artery are potential recipient vessels for microvascular free flap transfer for soft tissue coverage of the lower leg: the anterior tibial, posterior tibial, and peroneal arteries (**FIG 1A–E**).
- Apart from the concomitant veins of the named arteries of the lower leg, the two major superficial veins, which are the long (great) and short (small) saphenous veins, may be used as recipient veins. The superficial veins run superficial to the fascia cruris (deep fascia) of the lower leg (**FIG 1F**).
- Sizable perforators to the overlying skin derived from any of the three major vessels can also be recipient vessels when they are found near the defect.^{1,2}
- The specific recipient vessels are chosen according to the site of the defect.
 - Upper third of the lower leg: the upper third of the lower leg is technically the most difficult zone for microvascular repairs because of the deep location of major vessels. A long vein graft from the flap passing proximally to the side of the femoral artery was commonly used in the past. However, sural vessels (**FIG 2**) and the reversed descending branch of the lateral circumflex femoral vessels can also be effective recipient options in this region.³
 - Middle third of the leg: the anterior tibial vessels are often used because the

vessels become more superficial as they descend (**FIG 3**). The posterior tibial arterial and venous system may be easily exposed after retraction of the soleus muscle when the defect is on the medial side of the leg (**FIG 4**).

- Distal third of the leg: distal branches of all three major vessels are easily accessible in this region because there is less overlying soft tissues, which also makes them more susceptible to injury in traumatic defects. The peroneal artery or its terminating calcaneal artery can also be used in the lateral region of the leg (**FIG 5**). Perforators from the peroneal artery can be used as recipient vessels in the lateral region (**FIG 6**).

FIG 1 • Main arteries and veins of the lower leg and incisions for exposure of recipient vessels. **A.** Three named arteries of the lower leg. **B.** Anterior tibial artery. **C.** Incisions for exposure of the anterior tibial artery. **D.** Incisions for exposure of the posterior tibial artery. **E.** Incisions for exposure of the peroneal artery. **F.** Long (A) and short (B) saphenous veins.

FIG 6 • A,B. Peroneal artery perforators for recipient vessel.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A multidisciplinary approach with comprehensive communication between the oncologist and/or orthopedic surgeon will allow better treatment outcomes.⁴
- Preoperative planning should be carried out by considering anticipated defect size, location, vascular anatomy, and comorbid conditions related to the outcomes of reconstruction.

IMAGING

- The authors routinely perform preoperative CT angiography to delineate the vascular anatomy of the lower extremity except when it is contraindicated.
- Detailed information of the vascular status helps determine proper reconstruction options and recipient vessels, which ultimately decreases the risk of reconstruction failure in the free flap transfer.⁵

SURGICAL MANAGEMENT

- Soft tissue stability and long-term durability are of paramount concern in the reconstruction of the lower leg.
- The simple method is not always the best and often, a more complex method of reconstruction, such as the free flap, is initially chosen to obtain better functional and aesthetic outcomes.
- Elaborate preoperative planning regarding recipient vessels, donor site, flap composition (cutaneous, fasciocutaneous, musculocutaneous, chimeric, composite flap), and positioning of the patient during the surgery is crucial for successful soft tissue reconstruction of the lower leg. A muscle chimeric perforator flap is useful for filling dead spaces created by soft tissue loss (**FIG**

5).⁶

- Vascular complications are significantly higher if anastomoses are carried out in the zone of injury, due to inflammation and trauma to recipient vessels. A sufficiently longer pedicle or vessel graft may be necessary to reach normal suitable vessels.
- Donor site morbidity should also be considered in the preoperative planning. The donor site that permits primary closure of the donor defect is always favored over the ones that require skin grafting. The exact measurement of the shape and size of the defect is valuable for donor tissue economy and acceptable aesthetic results at the recipient site. A customized flap may be effectively designed by using paper or transparent plastic template based on the final defect shape.
- The flap thickness can be controlled by defatting of the perforator flap at the time of inset, which facilitates aesthetic reconstruction. On the other hand, flap thickness can be controlled secondarily when tissue edema resolves completely.
- Fasciocutaneous flap vs muscle flap in contaminated wounds: A previous animal study demonstrated that muscle flaps have advantages over the fasciocutaneous flap for contaminated wounds.⁷ However, recent studies show that there is no difference in bacterial eradication and quality of wound healing between muscle and fasciocutaneous flap use.^{8,9}
- There is a controversy regarding how early a soft tissue defect should be closed in lower extremity trauma. Early definitive soft tissue coverage may be necessary where vital structures such as blood vessels and peripheral nerves or hardware are exposed.¹⁰ The recent advent of negative pressure wound therapy has helped provide additional time for better delineation of nonviable tissues before final reconstruction in large, complex open wounds.¹¹

Preoperative Planning

- Vascular anatomy and degree of atherosclerosis are evaluated by preoperative CT angiography (**FIG 7**).
- Donor site and components of the flap are often decided preoperatively according to predicted defect size, location, type of tissue requirement, required pedicle length, surgeon's expertise, and patient preference.
- Rectus abdominis, latissimus dorsi, and the gracilis muscle flaps have been commonly used for lower leg reconstruction. Popular cutaneous or

fasciocutaneous flaps for lower leg reconstruction are the radial forearm, sural, anterolateral thigh, and thoracodorsal artery perforator (TDAP) flaps.^{8,12–14} Each flap has its advantages and disadvantages.

FIG 7 • CT angiography of the patient described in the surgical technique in the text. All three main vessels of lower legs are patent, and no atherosclerosis or vascular occlusion exists in both lower legs.

FIG 8 • Positioning of the patient when the flap is to be harvested from the ipsilateral back.

Positioning

- Patient position is influenced by the donor site selection and planned recipient vessel approach. The lateral decubitus position is convenient for harvesting flaps from the back nourished by the subscapular vascular tree. When the

medial approach is used for the recipient vessel, such as the posterior tibial vessel or medial sural vessel, the contralateral side of the back is the favored donor site. When the anterior or lateral approach is to be used for the anterior tibial artery or peroneal artery branches, it is better to harvest the flap from the ipsilateral back, which helps to avoid patient repositioning during the free flap surgery (**FIG 8**).

- A tourniquet is usually applied on the thigh during defect preparation including debridement and recipient vessel approach.

TECHNIQUES

Video p7-c025

■ Wound Preparation

- Recipient vessel decided on preoperative planning is checked for patency using a handheld audible Doppler.
- The ultimate defect is made by the complete debridement or excision of pathologic, necrotic, or infected tissues under tourniquet control (**TECH FIG 1**).
- Limited undermining of the skin flap around the wound margin is performed to facilitate subsequent flap inset.

TECH FIG 1 • A,B. Wound preparation for free flap reconstruction.

■ Recipient Vessel Preparation

- Approach to recipient vessels
 - When the defect is extensive such as in oncologic resection or located in the distal lower leg over the course of the major vessel, the recipient vessel can be harvested directly inside the wound, which is advantageous for avoiding added incisional scars.
 - An incision extending from the defect may be used when the adjacent recipient vessel is to be utilized. A separate incision with subcutaneous tunneling may be effectively employed for distant recipient vessel approach.
- Anterior tibial vessels are exposed through a dissection through the intermuscular septum between the tibialis anterior and extensor digitorum longus muscles (**TECH FIG 2**).
- The deep peroneal nerve is carefully separated from the anterior tibial artery and veins.

TECH FIG 2 • Recipient vessel preparation. Anterior tibial vessels are exposed through a dissection through the intermuscular septum between the tibialis anterior and extensor digitorum longus muscles.

■ Assessment of the Defect

- The tourniquet is deflated and meticulous hemostasis is performed. Irrigation with saline solution is carried out.
- Defect size along with its shape can be exactly measured using transparent plastic or paper template, which will be used for flap design in the donor site.
- Dead space that needs to be filled is also marked on the defect template.

■ Flap Harvest

- Outline of relevant muscles and landmarks are marked on the skin (**TECH FIG 3A**).
- Perforators are located using handheld pencil Doppler and the flap is designed using the template of the defect.
- Once the targeted perforator is identified via a suprafascial dissection through a limited incision on superior border of the flap, then the whole skin paddle is elevated and meticulous intramuscular dissection of the pedicle with bipolar forceps is commenced.
- Motor nerve branches to the muscle are maximally preserved and the pedicle is divided when sufficient length is obtained (**TECH FIG 3B**).
- A closed suction drain is placed, and the donor wound is primarily closed in

layers (**TECH FIG 3C,D**).

TECH FIG 3 • **A.** Design of the flap using transparent plastic template. **B.** Elevated TDAP flap. **C.** Defect of the donor site after elevation of the TDAP flap. **D.** Primary closure of the donor site.

■ Microanastomosis With Temporary Inset (**TECH FIG 4**)

- Temporary inset of the flap is performed using a skin stapler.
- It is important to avoid twisting or kinking of the pedicle. A useful way to mitigate twisting of the pedicle is to lift and hold the flap in the air and allow the vessels to dangle and unwind. If the pedicle is long, lazy-S-shaped positioning of the pedicle under the flap is performed to avoid kinking of the pedicle.
- Vascular tension should be avoided through prudent planning, harvesting a sufficient length of the pedicle, and judicious use of a vascular graft when needed.

- Wide exposure of the field and ensuring a conducive atmosphere are critical for successful microvascular anastomosis.
- End-to-side anastomosis of the artery is preferred to maintain vascular flow in inherent arteries of the leg and to avoid iatrogenic ischemic complications of the leg.
- The deep vein system (comitantes vein) is usually given the first consideration because of the special convenience with dissection and inset. However, the superficial veins (long saphenous and short saphenous veins) can be used when there is significant size mismatch with the deep veins or if no adequate deep vein is suitable. Regardless of the use of the deep or superficial veins, the quality of the recipient vein should be checked based on intraoperative findings such as the absence of scarring around the vein, existence of backflow, absence of thrombi, and absence of resistance to an intraluminal heparinized saline flush.¹⁵
- The vascular clamp is removed after completion of the anastomosis. Warm saline is irrigated onto the vessels and flap, followed by waiting for several minutes to check patent inflow and outflow of the flap.
- Meticulous hemostasis is performed under the microscope to ensure that branches of the pedicle and recipient vessels are secured as hematoma is known to be one of the main causes of re-exploration after free flap reconstruction in lower extremities.¹²

TECH FIG 4 • A. Temporary inset of the flap for microvascular anastomosis. **B.** After completion of microvascular anastomosis. End-to-side anastomosis of the artery and end-to-end anastomosis of the vein were carried out.

■ Final Inset

- If a flap is too bulky, then meticulous defatting of the perforator flap can be performed at the time of insetting. The deep fat, superficial fascia, and deep layer of superficial fat can be safely removed, but not the area near the perforators (about 2–3 cm diameter), using scissors with or without loupe but microscope magnification is not usually necessary (**TECH FIG 5A**). This is a crucial procedure for obtaining a satisfactory contour of the reconstructed lower leg. However, to completely avoid tissue damage within the flap and risk of ischemic complication at the initial operation, secondary procedure for thinning is an alternative option.
- The final inset of the flap needs to be carefully performed because the pliability and extensibility of the flap may change after the defatting procedure.¹⁶ Excessive flap tissue is diligently excised to yield a more natural appearance (**TECH FIG 5B,C**).
- The wound is closed by placing drains under the flap to prevent fluid collection.
- A leg splint is frequently applied for immobilization. An elastic bandage is loosely applied. Part of the flap is left open for postoperative monitoring of the flap (**TECH FIG 5D**). Excessive compression over the vascular pedicle should be avoided.

TECH FIG 5 • **A.** Defatting of the perforator flap. **B,C.** Immediate postoperative photos. **D.** Dressings of the reconstruction site.

PEARLS AND PITFALLS

Planning

- Elaborate preoperative planning of recipient vessels, donor site, flap composition, and positioning of the patient is important for successful reconstruction.
- A multidisciplinary approach including comprehensive communication with the oncologist and/or orthopedic surgeon will allow better treatment outcomes.

Flap design

- The exact template created according to the final defect size and shape is helpful to avoid harvesting an unnecessarily large flap and to obtain an aesthetically pleasing contour of the lower leg.

Placement of the pedicle

- It is important to avoid twisting of the vascular pedicle.
- If the pedicle is excessively long, it is placed in a lazy-S-shaped position under the flap to avoid kinking of the

	pedicle. ■ Minimize tension on the pedicle. Sufficient acquisition of the pedicle can be a safe strategy.
Microanastomosis	■ End-to-side anastomosis of the artery is preferred to maintain distal vascular flow in named arteries of the lower leg and to avoid potential ischemic sequelae of the leg. ■ The deep vein system (venae comitantes) is usually given the first consideration as a source of outflow because of special convenience for dissection and inset and because it is less vulnerable to trauma than the superficial venous system.
Flap inset	■ Defatting of the perforator flap is a valuable technique for obtaining an aesthetic contour at the time of inset, but must be done meticulously to avoid compromising perfusion. ■ Dimensional excess of the flap is diligently corrected by careful trimming.
Hemostasis	■ Meticulous hemostasis needs to be performed during the entire surgical procedure because hematoma is known to be one of the main causes of re-exploration after free flap reconstruction in lower extremities.

POSTOPERATIVE CARE

- Proper patient positioning and avoidance of vascular pedicle compression (by splinting or inattentive wound dressings) play vital roles in the postoperative period.
- The leg is elevated for better venous return and to minimize edema while the patient is lying in bed.
- There is no consensus regarding the use of medications for thromboprophylaxis, such as aspirin, heparin, and dextran. The authors do not routinely use any of these medications.
- Enoxaparin (low molecular weight heparin) is considered for deep vein thrombosis prophylaxis in lower extremity reconstructions as chemoprophylaxis is recommended for general surgery patients scoring 3 or higher on the Caprini scale.¹⁷ Patients undergoing lower extremity reconstruction with free flap frequently fall into the high-risk group with Caprini scores of 5 or greater.¹⁸
- Postoperatively the flap can be monitored every 1 to 3 hours for the first 48 hours, and every 4 to 6 hours for the next 48 hours after the surgery. Monitoring is typically performed by physical examination and handheld

pencil Doppler.

- An oral diet is allowed 24 hours after surgery.
- Although the duration of immobilization time varies based on the orthopedic and bony injuries, generally progressive weight bearing and ambulation are achieved once the flap maturation is assured, which occurs in 2 to 3 weeks for isolated soft tissue reconstruction.

OUTCOMES

- Microvascular free flap for lower extremity reconstruction is currently a safe and reliable procedure with a high success rate. Recent advancements in technology and improvement in surgical techniques have led to reported success rates of between 94% and 100%.^{5,8,12,19}
- Microvascular free flap is a reliable reconstructive option for defects of various sizes in various locations of the lower leg, and multiple tissue components such as cutaneous, muscle, and muscle chimeric can be used according to tissue requirements (**FIG 9**).

FIG 9 • Cases of lower leg reconstruction with free flaps. **A.** Dual-pedicled deep inferior epigastric artery

perforator (DIEP) flap for extensive lower leg defect. Dual pedicles were anastomosed to the posterior tibial artery and vein with the end-to-side method. **B.** Reconstruction of small defect with TDAP flap. Anterior tibial vessels were used as recipient vessel. **C.** Reconstruction of extensive defects on the proximal lower leg using the DIEP flap. Medial sural vessels were used for recipient vessels, and the great saphenous vein was used for superdrainage. **D.** Reconstruction of the distal lower leg using the TDAP flap. Anterior tibial vessels were used as recipient vessels. **E.** Free muscle (latissimus dorsi) flap with skin graft. **F.** Muscle chimeric TDAP flap for distal lower leg reconstruction.

COMPLICATIONS

- Vascular-related complications such as venous and arterial thrombosis
- Hematoma: Early diagnosis of a hematoma under the flap is critical so that it can be evacuated promptly to prevent the compression and obstruction of the anastomotic site from the expanding hematoma. In particular, any time a postoperative hematoma is noted, the surgeon must consider venous thrombosis.
- Infection
- Partial flap necrosis

26 Soft Tissue Coverage of Lower Leg—Soleus Flap

CHAPTER

Rahim Nazerali and Lee L. Q. Pu

DEFINITION

- Mathes and Nahai type II muscle
- Most commonly proximally based pedicled flap, but a distally based flap has been reported.

ANATOMY

- Broad, large, bipennate muscle
- Deep to the gastrocnemius muscle in the posterior compartment of the leg
- Occupies major portion of superficial posterior compartment of the leg in the middle third tibial level
- Two separate muscle bellies, medial and lateral with separate origins
 - Origin
 - Lateral belly: posterior surface of the fibula
 - Medial belly: middle third of the medial border of the tibia
 - Insertion
 - Lateral belly: dorsal lateral aspect of the Achilles tendon
 - Medial belly: dorsal medial aspect of the Achilles tendon
- Vascular supply (**FIG 1**)
 - Proximal portion of muscle receives independent axial vascular supply to its medial and lateral bellies.
 - Dominant pedicle: muscular branches of the popliteal artery and from proximal two branches of the posterior tibial artery and peroneal artery
 - Distal portion of muscle primarily receives segmental blood supply from two to four segmental branches from the posterior tibial artery.

- Innervation
 - Motor: posterior tibial and medial popliteal nerves
- Function
 - Plantar flexion

FIG 1 • A schematic diagram shows the vascular anatomy of a soleus muscle.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Just like any other major flap surgery for the lower extremity, a patient's

general medical condition and neurovascular physical examination should be evaluated carefully.

- Previous orthopedic trauma to the leg and ongoing orthopedic procedures should also be taken into a consideration when planning a soleus muscle flap.

IMAGING

- Preoperative angiogram is recommended if using a distally based medial hemisoleus muscle flap to assess the blood supply, which is typically from branches of the posterior tibial vessels.

SURGICAL MANAGEMENT¹⁻⁷

- Soleus is the standard muscle flap of choice for middle third defects of the leg.
- Numerous limitations with bulk, arc of rotation and weakening of plantar flexion when using the entire muscle.
- Medial hemisoleus muscle flap can be elevated based either proximally or distally depending on the location of the soft tissue reconstruction required.
- Medial hemisoleus muscle flaps should be chosen to reconstruct a less extensive wound (less than 50 cm² in most adult patients).
- Proximally based flaps can be used to cover middle third tibial wounds in the leg, whereas distally based flaps can be used for distal third defects. In addition, proximally based flaps can also be used to cover distal third defects if done properly.

Preoperative Planning

- Physical exam including pulse, neurological status, tissue quality
- Ensure that the soleus muscle has not been traumatized from previous injury.
- Standard ABI/TBI exam
- Evaluate and treat concerns for hardware infection or osteomyelitis.

Positioning

- Frog leg positioning

Approach

- Elevate under tourniquet control.
- Longitudinal skin incision made 2 cm medial to the medial border of the tibia and parallel to the tibia.
- Only the muscular portion of the soleus muscle is used as the flap, whereas the

tendon portion of the flap is left intact.

■ To cover a wound at:

- Middle and distal third of the leg: medial hemi-soleus muscle flap is elevated to the level just below the junction between the proximal and middle third of the leg for a middle third defect or just above the junction between the middle and distal thirds of the leg so that an adjacent perforator from the posterior tibial vessels to the flap can be preserved (**FIG 2A**).
- Distal third of the leg: medial hemi-soleus muscle flap is elevated only to the level just below the junction between the middle and distal thirds of the leg, preserving as many major perforators to the flap as possible, even in the distal third of the leg while allowing adequate arc of flap rotation (**FIG 2B**).

FIG 2 • A. Flap dissection and blood supply to the proximally based medial hemi-soleus muscle flap. The flap receives its blood supply primarily from the posterior tibial vessels. The flap also receives additional blood supply from one or two perforators from the posterior tibial vessels to its distal portion. **B.** Flap dissection and blood supply to the distally based medial

hemisoleus muscle flap. The flap receives its blood supply primarily from the most distal two perforators of the posterior tibial vessels. The flap also receives additional blood supply from the proximal source in a retrograde fashion.

TECHNIQUES

■ Proximally Based Medial Hemisoleus Flap^{1-3,5,6}

- Identify and dissect free from medial gastrocnemius muscle.
- Divide distally at the level of the junction between middle and distal thirds of the leg for covering a middle third defect of the leg or at the level close to the Achilles tendon if covering the distal third of defect in the leg.
- Medial half of the muscle is split longitudinally along with a raphe between the bellies of the soleus muscle.
- Only one or two distal perforators from the posterior tibial vessels to the medial hemisoleus muscle are divided so the flap rotation can be facilitated, but proximal major perforators should be preserved to maximize the blood supply to the flap (**TECH FIG 1A**).
- The spared tendon is approximated to the remaining lateral half of the soleus muscle with nonabsorbable sutures in a figure of eight fashion to help minimize the functional loss of the leg after flap harvested (**TECH FIG 1B**).
- The elevated hemisoleus muscle flap can be rotated to cover the defect and a split-thickness skin graft can be placed after flap transfer.

TECH FIG 1 • A. Intraoperative view shows an adjacent perforator (indicated by forceps) from the posterior tibial vessels to the medial hemisoleus muscle flap. Preservation of this perforator can be critical to ensure an adequate blood supply to the distal flap. **B.** The spared conjoint tendon is approximated to the remaining lateral half of the soleus muscle with sutures to minimize the functional loss of the leg after flap elevation.

■ Distally Based Medial Hemisoleus Flap^{3,4,6}

- Preoperative angiogram can be helpful for determining the presence of major perforators from posterior tibial vessels to the distal portion of the medial soleus muscle.
- Only one or two distal perforators from the posterior tibial vessels to the medial hemisoleus muscle are divided so the flap turnover can be facilitated; however, one adjacent proximal perforator should be preserved to maximize the blood supply to the flap (**TECH FIG 2**).
- The medial hemisoleus muscle flap is transposed or turned over into the defect and inset with absorbable half-buried horizontal mattress sutures. Scoring the fascia over the medial hemisoleus muscle belly can produce a few more centimeters of arc of rotation. The muscle flap is covered immediately with a split-thickness skin graft after flap transfer.

TECH FIG 2 • Intraoperative view shows the first large perforator (indicated by forceps) from the posterior tibial vessels to the distally based medial hemisoleus muscle flap. This perforator serves as a pivot point of the flap turn over and should be well preserved. Preservation of this perforator can be critical to ensure an adequate blood supply to this distally based flap.

PEARLS AND PITFALLS

Muscle damage

- Before dissecting the medial hemisoleus muscle flap, the surgeon should make sure that the soleus muscle has not been traumatized from the previous injury.

Blood supply

- When performing a proximally based flap, any perforators from the posterior tibial vessels to the distal medial half of the soleus muscle just at or above the level

of a tibial wound should be preserved while allowing adequate arc of flap rotation to cover a wound in the distal third of the leg.

- The modifications of surgical techniques emphasize the preservation of an adequate blood supply to the distal portion of the medial hemisoleus muscle flap after the flap is elevated. These techniques would maximize reliability of the medial hemisoleus muscle flap and expand its role in reconstruction of a wound in the distal third of the leg. With the aid of a preoperative angiogram, major perforators in the lower third of the leg can be identified when planning a distally based medial hemisoleus flap.
- The most proximal perforators from the posterior tibial vessels to the medial half of the distal soleus muscle within the upper distal third of the leg should be preserved while allowing adequate flap turnover to cover a tibial wound in the distal third of the leg. This perforator will serve as a pivot point for flap turnover and the level of the perforator will determine how far this flap can reach.
- The modified surgical techniques in flap dissection emphasize the preservation of an adequate blood supply to the distal portion of the distally based flap and maximize reliability of the medial hemisoleus muscle flap even when it is based distally.

Free tissue transfer^{8,9}

- Free tissue transfer should still be considered for a larger soft tissue wound in the middle or distal third of the leg or for a less extensive wound when either the soleus muscle or those perforators from the posterior tibial vessels are traumatized.

POSTOPERATIVE CARE

- Place patient in knee and ankle immobilizer with minimal pressure on the transposed flap.
- Effective leg elevation to reduce edema
- Placement of a warming unit around leg to maintain a warm temperature
- Monitoring frequently with clinical assessments

OUTCOMES

- Based on the author's experience, the proximally based medial hemisoleus muscle flap can be used for a relatively proximal tibial wound in the junction of the middle and distal thirds or in the distal third of the leg.
- The flap is fairly reliable and can often be done within 2 hours. In addition, the flap can provide just enough muscle bulk for soft tissue coverage of the tibial wound, and thus, reconstructive outcomes are usually quite good (**FIG 3**).
- The distally based flap can be used for a less extensive distal tibial wound (often close to the medial malleolus) in the distal third of the leg. The flap can be reliable in most healthy and compliant patients.
- The initial venous congestion may also become a problem in certain patients such as smokers or those with an inability for leg elevation during the postoperative period.
- In general, the distal flap necrosis occurs infrequently if the flap is proximally based but occurs in about 20% of the patients if the flap is distally based (**FIG 4**).

COMPLICATIONS^{3,4,6}

- Like any other pedicled flaps, the distal flap necrosis may occur, but total flap loss should not happen.
- The distal flap necrosis is usually insignificant and can be managed with debridement.
- The flap can then be readvanced adequately to cover the wound, and the final outcome can still be good.
- Further advancement of the flap is possible by dividing the most proximal perforator, which has served as a pivot point since the flap has been “delayed” after initial flap elevation.

FIG 3 • **A.** A male patient had a 12 × 6-cm soft tissue defect in the middle third of the leg with exposed fracture site. **B.** A proximally based medial hemisoleus muscle flap was elevated and rotated to cover the defect. **C.** Completion of the muscle flap inset before placement of skin graft. **D.** Result at 3.5-month follow-up.

FIG 4 • A. A female patient had a 6 × 5-cm soft tissue defect in the distal third of the leg with exposed fracture site. **B.** A distally based medial hemisoleus muscle flap was elevated and turned over to cover the defect. **C.** Completion of the muscle flap inset before placement of skin graft. **D.** Result at 2-month follow-up before subsequent bone grafting.

Section III: Knee

27 Nerve Repair and Reconstruction—Tibial Nerve

CHAPTER

Shawn Moshrefi and Catherine Curtin

DEFINITION

- Tibial nerve injuries can vary in severity, mechanism, and treatment.
- Nerve injury categories¹
 - Neurapraxia: conduction delay with no axonal injury. These injuries will recover spontaneously without intervention.
 - Axonotmesis: axonal injury resulting in disruption of the axons, but the supporting nerve scaffolding is intact. In these injuries, distal nerve segment will undergo Wallerian degeneration and proximal fibers will regenerate. Spontaneous recovery is possible.
 - Neurotmesis: complete disruption of the nerve. In these injuries, spontaneous regeneration will *not* occur.
 - Neuroma in continuity: disruption of the axons though the scaffolding seems to be intact. However, at the injury site, there is internal fibrosis, which prevents axons from regenerating. In these injuries, spontaneous regeneration will *not* occur.
 - Mixture of injury types: nerve patterns can be complex and one nerve can have several different types of injury.

ANATOMY (FIG 1)

- Tibial nerve originates from L4 through S3 nerve roots.
- The motor branches innervate the posterior calf compartment muscles and the majority of small muscles in the foot.

- The sensory branches supply the knee joint, part of the sural nerve distribution, and the sole of the foot.
- Tibial nerve branches from the sciatic nerve in the popliteal fossa.
- The first branch off the tibial nerve is a sensory contribution to the sural nerve.
- The next branches are the motor nerves to the gastrocnemius muscles.
- Then, the tibial nerve passes through popliteal fossa under arch of soleus. (This area is a potential area of tibial nerve entrapment called the *soleal sling*.)
- The tibial nerve courses distally adjacent to the tibia on undersurface of soleus in the leg running with the peroneal artery and vein.
- At the ankle, tibial nerve is posterior to the medial malleolus adjacent to posterior tibial artery beneath the flexor retinaculum (This is a potential area of entrapment known as the *tarsal tunnel*.) (**FIG 2**).

FIG 1 • Anatomy of the proximal tibial nerve.

- At the medial malleolus, the tibial nerve branches into the calcaneal, medial plantar, and lateral plantar nerves. The anatomy of the branching is highly variable between patients.²

FIG 2 • Anatomy of the tarsal tunnel.

PATHOGENESIS

- Tibial nerves can be injured in many ways and in any location along its course. Listed below are some of the more common causes of tibial nerve injury.
 - Traumatic knee dislocation
 - Direct trauma to the popliteal area, both blunt or sharp
 - Iatrogenic prolonged tourniquet, hardware, or limb lengthening procedures
 - Ankle swelling or compression
 - Cysts or other nerve compressing structures (both in the popliteal fossa as well as at the medial malleolus)

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete and thorough history detailing patient's history of present illness, current injuries, history of prior injuries, prior surgeries (including spinal, buttock, and lower extremity procedures), comorbidities, occupation, and other case-by-case considerations should be obtained.
- Inspection
 - Is the calf or foot swollen?
 - Are there vascular changes?
 - Is there atrophy?
- Vascular exam—palpable pulses distally, temperature, and capillary refill of the toes and foot.
- Sensory exam—Ten test: an area of normal or baseline sensation is compared to an area of concern for sensory loss and the difference is rated from 1 to 10 with 10 being the best score possible.³
- Motor exam
 - Test the respective muscles that the tibial nerve and its branches supply (tibial nerve controls plantar flexion and inversion of the foot and ankle).
 - Each individual movement tested should be compared to the contralateral side. This allows the examiner to identify subtle weakness.
 - Motor examination remember mnemonic TIP = **T**ibial **I**nverts and **P**lantar flexes.
- Scratch collapse test.⁴ This tool originally described for the upper limb is also useful for assessing nerve entrapment in the lower limb. For this test, the examiner is testing external rotation of the arm.
 - To do this, the examiner has the patient sitting straight with arms adducted to their side and elbows bent to 90 degrees. The patient is told to keep the arm in this position.
 - The examiner then gently scratches the skin directly over the area of suspected nerve compression (eg, posterior to the medial malleolus for suspected tarsal tunnel).
 - After scratching the skin, the examiner then directly applies internal rotation force to the patient's dorsal forearm while the patient actively attempts to resist. The test is positive for nerve pathology if the patient is briefly unable to resist your force of internal rotation.
- Tinel sign
- Point tenderness: the tibial nerve can be compressed at the level of the soleal

sling. Patients are often tender to direct pressure over the site (posterior midline of the calf about 10 cm distal to the posterior knee crease).

IMAGING/STUDIES

- X-rays are obtained if there is a suspected bony injury.
- MRI can assess for soft tissue masses such as Baker cysts and also provide information on the nerve.
- Enhancement of fascicles on MRI can help identify tibial neuritis (**FIG 3**).
- MRI is increasing in resolution and is taking an increasing role in identifying nerve pathology (**FIG 4**).

FIG 4 • Comparison of 3T and 7T MRI of tibial nerve. (Courtesy of Daehyun Yoon, Stanford University.)

FIG 3 • MRI of tibial nerve at soleal sling. Note that the tibial nerve is bright like the surrounding vessels, and normal nerve is isointense with the muscle. (Courtesy of Sandip Biswal, Stanford University.)

- Nerve conduction studies and electromyography (NCS/EMG) are a mainstay in the workup of nerve injury.
- NCS/EMG useful for closed nerve injury
 - Studies are performed at 4 to 6 weeks to achieve a baseline and assess type and severity of the injury.

- If there is no recovery on physical exam, the nerve studies are repeated at 3 months.
- If there is evidence of recovery, close follow-up is continued. If no signs of recovery at three months, operative intervention should be considered. Motor endplates begin to permanently degenerate at 3 months; thus, if surgery is required, earlier intervention improves functional outcomes.

DIFFERENTIAL DIAGNOSIS

- Spinal pathology
- Sciatic pathology
 - If on physical exam there are deficits in both peroneal nerve and tibial nerve distributions, then suspect possible sciatic pathology.
- Neurologic problems
 - Peripheral neuropathy
 - Motor neuron disease

NONOPERATIVE MANAGEMENT

- For closed nerve injuries, treatment starts with nonoperative management.
- Therapy
 - Edema prevention with lightly compressive wraps/garments and physical therapy with massage may be helpful.
 - Range of motion exercises to maintain supple joints and prevent the nerve from scarring.
 - Desensitization to decrease areas of sensitivity.
- Orthotics
 - Custom splint that keeps the hindfoot in the neutral position in order to maintain function and minimize discomfort.
 - Shoe inserts are a first step in people with suspected tarsal tunnel.

SURGICAL MANAGEMENT

- Surgical treatment is used for open nerve injuries, closed nerve injuries that are not showing any signs of recovery at 3 months, and nerve compressions that did not respond to conservative measures.

Preoperative Planning

- Definitive fracture fixation should be performed prior to nerve repair.
- Arterial injury should be treated prior to nerve repair.

- If possible, use of a lower extremity tourniquet is advisable to aid in visualization of injury.
- If intraoperative nerve monitoring is planned, inform anesthesia team to not use paralytics.

Positioning

- Positioning depends on level of injury (above knee, at level of the knee, or below knee).
- Access to popliteal area is easiest with the patient in the prone position.
- Access to the soleal sling is managed with the patient supine, hip externally rotated, and knee bent.
- Access to tarsal tunnel is managed with the patient supine.

Approach

- For the posterior knee approach, a curved incision rather than a straight incision across the joint is required to prevent scar contracture that can limit mobility.
- For access to the soleal sling, a medial incision on the posterior border of the tibia starting just distal to the tibial plateau (**FIG 5**).
- The tarsal tunnel is accessed posterior to the medial malleolus.

FIG 5 • Incisions for soleal sling and tarsal tunnel release.

■ Repair of Acute Traumatic Injury to Tibial Nerve

- Patient positioned supine.
 - Tourniquet placed above the knee.
 - If a wound is present, incorporate wound into exposure.
 - If wound orientation or access is inadequate, then either extend wound incision to match standard approach or create counter incisions.
 - Resect any damaged or scarred nerve until two healthy nerve ends are revealed. (The proximal healthy end should have fascicles clearly seen bulging out the end of the nerve.)
 - Use microsurgical technique to handle the nerve and align the internal fascicle anatomy.
 - Perform a tensionless repair. (If the 9-0 nylon suture cannot hold the repair, there is too much tension).
 - If there is a nerve gap, harvest a sural nerve graft.
 - Cable the graft and suture in place with a few 9-0 nylon sutures using microscopic technique.
 - Augment repair by sealing coaptation site with fibrin glue.
 - Closure of wound.
 - Place in a leg splint or knee immobilizer to protect repair.
-

■ Release of Soleal Sling⁵

- Anesthesia options: regional anesthetic (popliteal/distal sciatic block and saphenous block) or general anesthesia
- Patient is supine and the hip is externally rotated, exposing the medial side of the leg.
- A thigh tourniquet is placed.
- The incision is placed at the medial tibial plateau and runs distally for about 10 cm and is placed about 1 cm posterior to the medial edge of the tibia (**TECH FIG 1A**).
- The subcutaneous tissue is carefully dissected, preserving the saphenous nerve and vein.
- The fascia over the gastrocnemius is opened and the plane between the soleus is identified.

- The gastrocnemius is retracted out of the way.
 - The soleal sling can be palpated with a finger as a fascial notch in the proximal border of the muscle.
 - The medial soleal muscle is reflected and perforating vessels are clipped.
 - The tibial nerve is identified and a vessel loop is placed.
 - Constricting fascial bands are released over about a 5 cm length.
 - Skin is closed and a bulky dressing placed.
 - Early ambulation is encouraged.
-

■ Release of Tarsal Tunnel

- Patient is placed supine.
- Regional block of the popliteal and saphenous nerve is performed.
- Tourniquet is placed on the calf.
- A bent incision is placed posterior to medial malleolus.
- Skin and subcutaneous tissue are divided.
- Care is taken to preserve the overlying sensory nerves.
- The flexor retinaculum is incised proximally and the posterior tibial vessels are visualized below. Small crossing vessels are clipped.
- The nerve is identified deep to the vessels and a loop is placed around the nerve.
- The dissection is taken distally and the branches are identified. (Note the calcaneal branches have variable anatomy and number) (**TECH FIG 1B**).
- The medial and lateral plantar nerves are identified and loops placed.
- The fascia overlying the medial and lateral plantar nerves is divided including the fascia overlying the abductor hallucis.
- All fascia must be released distally and the dissecting scissors can easily fit in the tunnels over the medial and lateral plantar nerves.
- Meticulous hemostasis is required.
- Closure and placement of a bulky dressing
- Early ambulation is encouraged.

TECH FIG 1 • A. Tibial nerve exposed through soleal sling. Note the deep exposure required. The tibial nerve is at the base of the wound identified by the forceps. **B.** Tibial nerve exposed in a tarsal tunnel release. Note the multiple calcaneal branches going posteriorly.

■ Tibial Nerve Traction Injury

- General anesthesia
- Thigh tourniquet (to obtain optimal nerve monitoring results the tourniquet needs to be released for 20 minutes). If tourniquet is not used, preinject with bupivacaine with epinephrine prior to prepping the patient.
- Prone positioning
- Intraoperative nerve monitoring should be available.
- Incision is angled from the center of popliteal fossa.
- The dissection is taken down to the level of the muscle fascia.
- The tibial nerve is identified as it branches off the sciatic nerve.
- A vessel loop is placed on the nerve and the dissection is taken distally.
- The nerve is released from the overlying scar (often a very challenging dissection). The dissection is taken posterior to the gastrocnemius muscles to release the soleal sling.
- Intraoperative nerve monitoring is performed. Starting with somatosensory evoked potentials can help establish the proximal level of intact nerve. Nerve to nerve monitoring can identify neuroma in continuity.
- If the nerve is ruptured or neuroma in continuity is identified, resect damaged or scarred nerve until two healthy nerve ends are revealed.

- Ensure that the proximal nerve is healthy by using the assistance of your neurologist performing the intraoperative nerve monitoring.
- If there is a nerve gap, harvest a sural nerve graft.
- Cable the graft and suture in place with 9-0 nylon sutures using microscopic technique.
- Augment repair by sealing coaptation site with fibrin glue.
- Closure of wound
- Place in a leg splint or knee immobilizer to protect repair.

PEARLS AND PITFALLS

Hemostasis (if no tourniquet)

- Preinject incision with bupivacaine with epinephrine.
- A solution of 1 amp of epinephrine diluted in 100 cc of saline can be used to moisten a gauze that is then dabbed in the wound to help with visualization.

Technique

- To ensure complete release of the tarsal tunnel, the distal compression of the medial and lateral plantar nerves must be released. The distal dissection is challenging due to the overlying vessels. Clip crossing vessels as needed to adequately expose the nerves.

Intraoperative monitoring

- Communication between neurology and anesthesia team is critical to ensure that patient does not receive medications that will hinder intraoperative monitoring.
- Sequential compression device machine and warming machines can cause background that interferes with intraoperative monitoring.
- Do not use tourniquet if planning intraoperative monitoring. The nerve can suffer neuropraxia after 30 minutes of ischemia.

Diagnosis

- MRI imaging can help if proximal nerve entrapment suspected.

POSTOPERATIVE CARE

- Postoperative splint utilized for 3 weeks if there is a nerve repair to protect
- Early mobilization for neurolysis patients
- Affected lower extremity should be elevated at all times initially to aid in

reduction of swelling.

- Multimodal pain management for postoperative pain
- Early therapy for desensitization, scar management, and nerve gliding

OUTCOMES

- The literature on results from tibial nerve surgery is sparse.
- Tarsal tunnel release is an effective procedure when performed properly. A case series found that patients improved their Maryland Foot Score from 61 to 80, 3 months after tarsal tunnel release.⁶
- Tarsal tunnel release can fail for several reasons including incorrect diagnosis, proximal compression, and intrinsic nerve damage.⁷

COMPLICATIONS

- Neuropathic pain
- Inadequate release
- Bleeding/hematoma

28 Excision of Soft Tissue Tumors of the Knee

CHAPTER

Raffi S. Avedian

DEFINITION

- Soft tissue sarcomas are malignant tumors that arise from mesenchymal cells and are classified according to their cell of origin such as muscle, tendon, or fat.
- Peripheral nerve sheath tumors arise from neural crest cells but are typically grouped with sarcomas because of similarities in location, natural history, and treatment.
- The World Health Organization groups soft tissue sarcomas into 10 categories based on the tissue of origin.
- Most sarcomas occur in a deep location, meaning below the muscle and fascia, whereas one-third of sarcomas occur in a subcutaneous location.
- Patients with soft tissue sarcomas and patients with benign tumors often present with the same chief complaint of having a soft tissue mass.
- Rendering an accurate diagnosis prior to surgery is important because the treatment plan may vary based on the nature of the diagnosis. For example, a benign tumor may be monitored or removed with a simple excision, whereas in the case of a sarcoma, the goal of surgery is to remove the tumor with a wide margin. With appropriate planning, radiotherapy and/or chemotherapy is often incorporated into the treatment plan either before or after definitive surgery.

ANATOMY

- The knee is the largest joint in the body. It is made up of the patellofemoral, lateral, and medial compartments.
- Knee motion is primarily flexion and extension; however, bending and rotation

are important components of knee kinematics.

- The primary stabilizers of the knee are the extra-articular medial and lateral cruciate ligaments and intra-articular anterior and posterior cruciate ligaments.
- The knee has several layers of covering including the capsule and retinacular tissues. During tumor resection, superficial layers may be used as the deep margin for the tumor, whereas the deeper capsule may be preserved to keep the joint closed.¹
- The popliteal artery travels along the back of the knee and along with the tibial nerve travels between the lateral and medial head of the gastrocnemius. It branches into the posterior tibial artery, which travels deep to the soleus muscles; the anterior tibial artery, which passes from posterior to the anterior compartment distal to the tibia-fibula joint; and the peroneal artery, which branches off the tibiofibular trunk and is located medial to the fibula next to the flexor hallucis longus.
- The geniculate vessels branch off from the popliteal vessels and are often all ligated during tumor resection of the distal femur.
- The tibial nerve is located next to the popliteal vessels. The common peroneal nerve travels medial and deep to the biceps femoris muscle, a constant relationship that facilitates finding and protecting the nerve during tumor dissection.
- The common peroneal nerve wraps around the neck of the fibula and divides into the deep branch that innervates the anterior muscle compartment and the superficial branch that innervates the lateral compartment.
- The lateral sural cutaneous nerve, which branches off the common peroneal nerve, may be large in some patients and be confused with the common peroneal nerve.

PATHOGENESIS

- The mechanism for sarcoma formation is not known.
- Risk factors for sarcoma development include radiation exposure such as medical radiotherapy, pesticide exposure, and hereditary conditions including Li-Fraumeni syndrome and neurofibromatosis.

NATURAL HISTORY

- All sarcomas have the potential for local recurrence and metastasis.
- Tumor variables that are associated with increased risk of metastasis include high grade and large size (greater than 5 cm).

- Lungs are the most common location of metastasis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Determining when the mass was first noticed and how rapidly it is growing can help the clinician differentiate between benign and malignant tumors.
- The presence of pain is often associated with a benign tumor, such as a schwannoma or vascular malformation, and may not be present with sarcomas until late in the disease course.²
- Determining the size of the tumor, manual muscle strength testing, and sensory examination are useful to determine if there is a neurological compromise. Limb edema assessment and pulse examination can help determine if the tumor is causing vascular or lymphatic compromise.
- Range of motion testing and gait assessment are helpful in assessing a patient's mobility and functional status to guide perioperative and postoperative counseling.

IMAGING

- Plain radiographs can help diagnose joint degeneration or joint-based lesions such as gout and synovial osteochondromatosis.
- Magnetic resonance imaging is the modality of choice for soft tissue tumor evaluation (**FIG 1A,B**).
- Fat-sensitive images such as T1-weighted sequences are best for identifying critical anatomic structures such as nerves and vessels.
- Fluid-sensitive images including T2-weighted and STIR sequences highlight pathology very well.
- Contrast-enhanced sequences are used to differentiate cystic from solid areas in tumors and identify reactive peritumoral edema, which will be high signal on fluid sequences but not enhance with contrast.
- Some benign tumors such as lipoma, lipoma arborescens, and schwannoma may be diagnosed on MRI; however, most soft tissue tumors require a biopsy for diagnosis.³

FIG 1 • A. Coronal and axial **(B)** MRIs demonstrating a high-grade soft tissue sarcoma abutting the proximal tibia and knee joint.

DIFFERENTIAL DIAGNOSIS

- Giant cell tumor of tendon sheath
- Synovial chondromatosis
- Lipoma arborescens
- Other benign tumors
- Sarcoma
- Reactive and inflammatory lesions such as gout or infection

SURGICAL MANAGEMENT

- The appropriate treatment for any musculoskeletal tumor is based on its diagnosis and natural history.
- Performing a surgery without consideration of the diagnosis and the appropriate margin may cause harm to patients.⁴
- In cases where MR imaging is not diagnostic, a biopsy should be performed.
- Treatment strategy including the use of preoperative radiation and specific surgical plan should be formulated by a multidisciplinary team specializing in sarcoma care.⁵
- Treatment of knee tumors may require resection of the joint capsule, extensor mechanism, and/or stabilizing structures such as the collateral ligaments. Reconstruction of these structures should be accounted in the operative plan.

Preoperative Planning

- A patient is considered ready for surgery after completion of staging and multidisciplinary review of pertinent imaging, pathology, and treatment strategy.
- The surgical plan is created by thorough study of the preoperative MR scan. A plane of surgical dissection is planned to remove the tumor in its entirety while maintain a clean margin around it.
- If the tumor encases important vascular structures, a plan for vascular reconstruction is made with a vascular surgeon.
- Anticipated soft tissue coverage needs are assessed such as skin graft, local rotation flap, or free tissue transfer.

Positioning

- The patient is placed in the supine position unless the tumor is in the posterior compartment in which case the patient is placed in the prone position.
- The site of a flap harvest must be completely isolated from the tumor site to avoid contamination and tumor spread. A separate back table and clean instruments should be used.

Approach

- The surgical approach varies based on location of the tumor.
- Previous biopsy and surgical scars are considered contaminated and must be excised en bloc with the tumor.

TECHNIQUES

■ Wide Resection of a Knee Sarcoma

- Most knee tumors are subcutaneous and require a paddle of skin to be removed as the superficial margin.
- An incision is made 2 to 3 cm peripheral to the edge of the tumor as determined by palpation and preoperative MRI (**TECH FIG 1A**).
- The dissection is carried through the subcutaneous fat angling away from the tumor (**TECH FIG 1B**).
- The deep fascia is identified and cut circumferentially around the tumor (**TECH FIG 1C**).

- For tumors abutting the joint capsule, the surgeon must assess if the tumor is adherent to the capsule, in which case the entire capsule must be removed, or if the tumor only abuts the capsule in which case only the retinaculum needs to be removed.
- Sutures may be used to secure the deep layer to the skin to prevent the tumor from “leaking out” of the superficial layer.
- Take care not to shear off the fat from the fascia during dissection.
- Avoid retractors on the tumor side of the dissection.
- Do not sacrifice margin in order to save tissue for a primary closure (**TECH FIG 1D**).
- Most surgeries require a skin graft or muscle flap for closure (**TECH FIG 1E,F**).

TECH FIG 1 • **A.** Planned skin incision. Notice the margin of skin around the palpable tumor. **B.** Superficial dissection of skin and subcutaneous tissue and identification of the common peroneal and lateral sural cutaneous nerves. **C.** The deep fascia is cut peripherally and a small cuff of muscle and retinacular tissue is removed as the deep margin. The muscular branches of the peroneal nerve are preserved. **D.** Defect after tumor removal. **E,F.** Lateral gastrocnemius muscle flap is rotated to cover the

defect and split-thickness skin graft applied.

PEARLS AND PITFALLS

Hematoma	■ Dead space after tumor removal should be managed with drains, muscle flap, free tissue transfer, or a combination of these techniques. ■ Seroma drainage in the clinic may be necessary.
Wound breakdown	■ Negative pressure dressings, aggressive dead space management, and maximizing patients' nutrition may reduce wound problems. ■ Patients should be counseled about potential need for reoperation for wound management.
Positive margins	■ Appropriate preoperative planning is important to minimize risk of unplanned positive margins. ■ Planned positive margins around critical structures such as nerves and vessels may be appropriate in certain settings.

POSTOPERATIVE CARE

- Mobilization and weight bearing depend on the extent of surgery.
- Extremity elevation is recommended while patient is in bed.
- Range of motion and therapy may begin after wound healing is sufficient.
- Postoperative radiotherapy, if needed, may be take place 4 to 6 weeks after surgery.

OUTCOMES

- Oncological outcomes include local recurrence and metastasis. Surveillance for recurrence should be managed by a multidisciplinary sarcoma team.
- Functional outcomes depend on the extent of tissue resection, patient overall health status, and late effects of radiation. Aggressive wound care and physical therapy may help maximize patient function.

COMPLICATIONS

- Wound healing problems that require operative intervention can occur in up to 33% of patients who undergo preoperative radiotherapy and 17% of patients who undergo postoperative radiotherapy.⁶
- Local recurrence occurs in a minority of patients and is more common in

patients with positive margins. Radiotherapy decreases the risk of local recurrence.

29 Excision of Bone Tumors of the Knee

CHAPTER

Raffi S. Avedian

DEFINITION

- Bone tumors of the knee may be benign or malignant (bone sarcoma) and exhibit a variable natural history ranging from latent to rapid growth.
- A bone tumor located in the distal femur or proximal tibia such that definitive treatment requires excision of part or all of the knee is discussed in this chapter.
- Treatment for a bone tumor of the knee requires reconstruction of the knee articulation.

ANATOMY

- The knee is the largest joint in the body. It is made up of the patellofemoral, lateral, and medial compartments.
- Knee motion is primarily flexion and extension; however, bending and rotation are important components of knee kinematics.
- The primary stabilizers of the knee are the extra-articular medial and lateral cruciate ligaments and intra-articular anterior and posterior cruciate ligaments.
- The popliteal artery travels along the back of the knee and along with the tibial nerve travels between the lateral and medial head of the gastrocnemius. It branches into the posterior tibial artery, which travels deep to the soleus muscles; the anterior tibial artery, which passes from posterior to the anterior compartment distal to the tibia-fibula joint; and the peroneal artery, which branches off the tibiofibular trunk and is located medial to the fibula next to the flexor hallucis longus.
- The geniculate vessels branch off from the popliteal vessels and are often all ligated during tumor resection of the distal femur.
- The tibial nerve is located next to the popliteal vessels. The common peroneal

nerve travels medial and deep to the biceps femoris muscle; a constant relationship that facilitates finding and protecting the nerve during tumor dissection.

PATHOGENESIS

- The mechanism for bone tumor formation is not known.
- Risk factors for sarcoma development include radiation exposure, radiotherapy, pesticide exposure, and hereditary conditions including Li-Fraumeni syndrome and retinoblastoma gene mutation.¹

NATURAL HISTORY

- Active benign tumors, such as giant cell tumor of bone, chondroblastoma, and aneurysmal bone cyst, will progress over time, may recur after excision, but are not lethal.
- All bone sarcomas have the potential for local recurrence and metastasis.
- Bone sarcomas have an *estimated incidence of 3260* in the United States.
- Lungs and other osseous sites are the most and second most common location of metastasis, respectively.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pain is a common presenting symptom for aggressive bone tumors.
- A thorough history and examination are important to assess duration of symptoms, comorbidities, physical dysfunction, organ involvement, overall health, and patient expectations in order to best tailor treatment strategy for the individual patient.
- Neurovascular examination is mandatory for any extremity tumor.

IMAGING

- Plain radiographs are used to formulate a differential diagnosis and a preoperative plan.
- Magnetic resonance imaging is routinely used to determine extent of intramedullary tumor involvement, presence of soft tissue extension, status of the neurovascular structures, and presence of tumor within the joint space.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis for a bone tumor includes benign tumors, sarcomas, lymphoma of bone, infection, and metabolic lesions (eg, hyperparathyroidism).
- The most common bone sarcomas are osteosarcoma, chondrosarcoma, and

Ewing sarcoma.

SURGICAL MANAGEMENT

- The appropriate treatment for any musculoskeletal tumor is based on its diagnosis and natural history.
- Biopsy incisions are considered contaminated and must be resected at the time of definitive surgery. Care should be taken to place the biopsy in a location that does not interfere with the final surgical plan.²
- If a bone sarcoma extends into the knee joint space by direct growth, pathological fracture, or iatrogenic contamination, an extra-articular resection (keeping the knee joint closed) should be performed.
- Reconstruction depends on the extent of bone excision and may include simple bone grafting, endoprosthetic implants, bulk allografts, osteoarticular implants, or vascularized fibula.
- The goal of surgery is to remove the tumor adequately to minimize recurrence and restore the mechanical integrity of the bone and joints so that the patient may have sufficient function to perform activities of daily living with minimal pain.

Preoperative Planning

- A patient is considered ready for surgery after completion of staging and multidisciplinary review of pertinent imaging, pathology, and treatment strategy.
- The surgical plan is created by thorough study of the preoperative radiographs and MR scan.
- Bone cuts are planned by measuring on preoperative imaging the distance from an intraoperatively identifiable landmark (eg, femoral condyle, epicondyle) to the desired osteotomy site.
- The soft tissue margin depends on the size and location of a soft tissue component to the tumor. For example, an anterior soft tissue mass along the distal femur can be safely resected by incorporating a portion of the vastus intermedius as the margin.
- When tumor abuts but does not encase blood vessels or nerves, they can be dissected free by leaving adventitia and epineurium on the tumor as the margin.

Positioning

- The patient is placed in the supine position; a hip bump may be placed if more

lateral exposure is desired.

- A sterile or nonsterile tourniquet may be used.
- A leg holder may be used in cases where an endoprosthetic knee replacement is being performed.

Approach

- The surgical approach varies based on location of the tumor.
- The guiding principles for the approach to the knee in the setting of a bone sarcoma are to maintain a sufficient margin around the tumor and preserve as much normal tissue as possible without sacrificing cancer treatment.
- Previous biopsy and surgical scars are considered contaminated and must be excised en bloc with the tumor.

TECHNIQUES

■ Distal Femur Resection and Endoprosthetic Reconstruction

- Tourniquet is used at the discretion of the surgeon by using gravity exsanguination rather than Esmarch to avoid tumor compression
- A longitudinal incision is made that includes a fusiform skin excision of the biopsy site. Skin flaps are created as needed to ensure adequate visualization of the tumor and critical anatomy.
- Soft tissue dissection around the tumor is performed with the following principles:
 - Adequate visualization must be achieved.
 - Margin of healthy tissue is kept on the tumor.
 - Nerves are dissected free; epineurium may be used as margin if tumor abuts the nerve. Sciatic nerve branches to hamstring muscles may be cut as needed to adequately mobilize the nerve away from the tumor.
 - Vessels are mobilized; adventitia may be used as margin if tumor abuts the vessels.
- Tumor removal may be broken down into four steps:
 - *Knee disarticulation*: perform an arthrotomy and cut collateral and cruciate ligaments, joint capsule, gastrocnemius origins, and popliteus tendon.

- *Neurovascular mobilization*: the popliteal vessels must be mobilized by dividing the geniculate branches and dissecting the vessels free from the adductor canal. The tibial nerve is located next to the vessels and the common peroneal nerve is located medial to the biceps femoris. They should be identified and mobilized away from the tumor as needed.
- *Muscle dissection*: often bone sarcomas of the distal femur or proximal tibia will have a soft tissue component. The muscle layer immediately covering the tumor is removed as the margin. For example, the vastus intermedius serves as good margin for anterior soft tissue masses. The lateral and medial intermuscular septa must be divided as close to the bone as tumor margin permits.
- *Osteotomy*: Measure the length of bone to be resected on preoperative MRI and translate that to intraoperative landmarks such as a measurement from the femoral condyle to the femoral diaphysis above the tumor. Bennett or Hohmann retractors are placed around the bone to prevent iatrogenic neurovascular injury and an oscillating saw is used to complete the osteotomy.
- The remaining posterior soft tissue attachments are cut, and the specimen is removed.
- Leg length can be restored by measuring the contralateral leg from the anterior superior iliac spine to the medial malleolus and recreating this on the operative side or measuring and recreating the length of bone removed from the affected side (**TECH FIG 1**).

TECH FIG 1 • Intraoperative photograph demonstrating technique for leg length recreation.

Trial implants are measured side by side with femur and tibial plateau to ensure what goes into patient matches exactly what was taken out.

■ Reconstruction

- The femur is prepared for endoprosthetic reconstruction using one of the currently available fixation techniques: a cemented stem, uncemented stem, or compress compliant prestress device (**TECH FIG 2**).
- Rotational alignment can be achieved by using the linea aspera as a posterior landmark. Also, trial implants may be placed and the knee taken through a range of motion check to ensure proper rotation of implants and patellar tracking. Once the surgeon is satisfied with the rotation, a mark is placed on the bone denoting anterior. This mark is used as a guide for correct insertion of the final implant.
- Deep drains are placed, and the deep fascia is closed over drains, followed by a subcutaneous fascia and dermal layer.

TECH FIG 2 • A. Anteroposterior radiograph of a 14-year-old boy with a distal femur osteosarcoma. **B.** Coronal MRI demonstrating large intramedullary extension and soft tissue mass. **C.** Sagittal MRI after induction chemotherapy demonstrating tumor extent and measurement for planned osteotomy. **D.** Axial MRI demonstrating soft tissue mass in vastus lateralis

and popliteal fossa abutting sciatic nerve and vessels. **E.** Intraoperative photograph after initial dissection around tumor, note a portion of the vastus lateralis is left on the tumor as a margin and the femur is exposed proximal to the tumor in anticipation of osteotomy. **F.** After osteotomy, the femur is lifted out of the wound to facilitated dissection of the posterior anatomy including the sciatic nerve and femoral vessels as they pass through the adductor canal. **G.** Photograph showing that the ligamentous structures of the knee including the capsule are identified and cut. **H.** Photograph of defect after tumor removal. **I.** Endoprosthetic reconstruction is performed including large metal segment to replace bone and a hinged total knee arthroplasty. **J.** Lateral radiograph 4 months after surgery.

■ Endoprosthetic Reconstruction of the Proximal Tibia

- The principles of distal femur tumor resection outlined in the previous section apply to resection of tumors of the proximal tibia.
- Unique aspects of proximal tibia resection include the following (**TECH FIG 3**):
 - Large skin flaps must be raised to visualize critical anatomy.
 - Patellar tendon must be detached from the tibial tubercle and subsequently reconstructed.
 - The popliteus muscle can be used as the margin covering posterior soft tissue masses.
 - The anterior tibial artery often must be ligated and divided as it branches from the popliteal artery at the lower border of the popliteus muscle.
 - The proximal fibula may be excised along with the tibia depending on the lateral extent of the tumor.
 - The patellar tendon may be repaired using 5-mm Mersilene tape sewed into

the tendon using Krackow stitches, the ends of which are then tied into the endoprosthesis.

- The repair may be reinforced using no. 5 nonabsorbable to sew the tendon down into additional holes in the endoprosthesis either directly or after cerclage around the patella.
- A gastrocnemius flap is elevated and rotated to cover the prosthesis and provide biological augmentation to the patellar tendon repair.
- A deep drain is placed, and the wound is closed in layers. A split-thickness skin graft is often needed to cover a portion of the gastrocnemius flap.

TECH FIG 3 • **A.** Anteroposterior radiograph of a 61-year-old man with a proximal tibia chondrosarcoma. **B.** MRI demonstrating tumor extent. **C.** Intraoperative photograph showing initial dissection including large skin flaps to enable adequate visualization. **D.** Deep dissection is performed by identifying the popliteal vessels and tibial nerve and mobilizing healthy muscle

away from the tumor. The soleus muscle is eventually detached along its insertion on the tibia and the gastrocnemius muscle is isolated in anticipation of rotational flap. **E.** Defect after tumor removal, notice the deep peroneal nerve has been preserved. **F.** The patellar tendon is secured to the implant with a 5-mm Mersilene tape using Krackow stitches and reinforced with no. 5 FiberWire. **G.** The gastrocnemius flap is brought over and secured in place making sure to cover the prosthesis and anchoring into the patellar tendon and joint capsule to maximize healing of the extensor mechanism. The wound was otherwise closed in layers over drains and a small skin graft was applied to the portion of the flap that remained exposed after skin closure.

PEARLS AND PITFALLS

Hematoma

- Dead space after tumor removal should be managed with drains, muscle flap, free tissue transfer, or a combination of these techniques.

Wound breakdown

- *Incisional negative pressure dressings*, aggressive dead space management, and maximizing patients' nutrition may reduce wound problems.
- Low threshold to debride draining wounds to minimize risk of prosthetic joint infection.

Positive margins

- Appropriate preoperative planning is important to minimize risk of unplanned positive margins.
- Planned positive margins around critical structures such as nerves and vessels may be appropriate in certain settings.

Venous thromboembolic events

- Risk of VTE compared to risk of hemorrhage into dead space should be balanced and patient counseled regarding risks.
- Aspirin and low molecular weight heparin are options for

	chemical prophylaxis.
	■ Mechanical compression is routinely used.
Prosthetic infection	■ Most common mode of failure in the long term. ■ May coat prosthesis with high doses of antibiotic bone cement at time of revision for local antibiotic delivery.

POSTOPERATIVE CARE

- Mobilization and weight bearing depend on the extent of surgery.
- Extremity elevation is recommended while patient is in bed.
- Range of motion and therapy may begin the first 1 to 2 weeks for distal femur reconstructions.
- Proximal tibia reconstructions require strict knee extension for 6 weeks to allow patellar tendon healing. Gradual knee flexion is begun at 6 weeks and progresses under the supervision of a physical therapist.
- May administer antibiotics while drains are in place.

OUTCOMES

- Oncological outcomes include local recurrence and metastasis. Surveillance for recurrence should be managed by a multidisciplinary sarcoma team. Local recurrence is higher when margins are positive.¹
- Functional outcomes depend on the extent of tissue resection and patient overall health status. Most patients will experience some form of disability that is proportional to the volume of muscle and bone resected.³
- Distal femur reconstructions do not require extensor mechanism reattachment and therefore generally function better than proximal tibia reconstructions.

COMPLICATIONS

- Prosthetic loosening may occur over time necessitating revision surgery. Generally, implant survival is approximately 80% at 20 years.
- Local recurrence occurs in a minority of patients and is more common in patients with positive margins.
- Deep infection can occur at any time after surgery and requires aggressive therapy including surgical debridement and antibiotic therapy to achieve limb salvage. Removal of implants may be necessary to eradicate infection.

Bony and Soft Tissue Debridement Around the Knee

CHAPTER

Derek F. Amanatullah, Michael J. Chen, Sahitya K. Denduluri, and James I. Huddleston

DEFINITION

- Several conditions affect the knee that requires meticulous soft tissue and bony debridement for treatment: these include open fractures, osteomyelitis, and infected total knee arthroplasty (TKA).
- The expertise of plastic surgeons is frequently needed for soft tissue management and coverage as the knee is relatively devoid of surrounding soft tissues in comparison to the muscle bound femur.

ANATOMY

- The knee is a complex synovial joint composed of two joints: the tibiofemoral and patellofemoral articulations.
 - The tibiofemoral articulation functions as a hinge joint allowing for flexion and extension with minimal rotation.
 - It transfers body weight from the femur to the tibia and can experience high joint reaction forces.
 - The patella is the largest sesamoid bone in the human body and transmits tensile forces from the quadriceps tendon to the patellar ligament.
 - By increasing the lever arm of the extensor mechanism from the center of rotation of the tibiofemoral joint, the patella reduces the amount of work the quadriceps have to perform to extend the knee.
- The distal femur is trapezoidal in shape with two condyles that articulate with the two condyles of the tibial plateau, forming the medial and lateral compartments of the knee. The majority of the weight is borne through the

medial compartment in a native healthy knee.

- The mechanical axis of the lower extremity is characterized by a straight line that passes from the center of the hip through the center of the ankle. Ideally, this line passes through the center of the knee.
- Compared to the hip, which is a ball and socket joint, the knee is a relatively incongruent and relies on both static and dynamic forces for rotational, sagittal, and coronal stability.
- The dynamic stabilizers are the muscles and their tendons that cross the knee joint: these include the hamstrings, the iliotibial band, the pes anserine, the two heads of the gastrocnemius, the popliteus, and the extensor mechanism.
 - These muscles provide stability through compression of the joint when they are activated.
 - The hamstrings are composed of the biceps femoris, which crosses the posterolateral aspect of the knee to insert onto the head of the fibula, and the semimembranosus, which inserts onto the posteromedial aspect of the tibial plateau.
 - The semitendinosus, also a hamstring muscle, crosses the medial aspect of the knee to insert onto the anteromedial proximal tibia along with gracilis and sartorius to form the pes anserine.
 - The iliotibial band forms from the coalescence of the gluteus maximus and tensor fascia lata and crosses the knee laterally to insert onto Gerdy tubercle, a prominence found just below the joint line on the anterolateral tibia.
 - The popliteus originates from the posterior aspect of the proximal tibia and inserts on to the lateral aspect of the lateral femoral condyle.
 - The two heads of the gastrocnemius cross posteriorly and insert onto the medial and lateral aspects of the distal femur.
- The static stabilizers include the ligaments and joint capsule.
 - The medial collateral ligament (MCL) extends from the medial epicondyle of the femur to the medial aspect of the proximal tibia metaphysis and resists valgus forces across the knee.
 - The posterolateral corner (PLC) of the knee resists varus and external rotational forces at the knee: its main components are the lateral collateral ligament, which extends from the lateral epicondyle of the femur to the proximal fibular head, the popliteus muscle, and the biceps femoris tendon.
 - The anterior cruciate ligament (ACL) extends from the posteromedial aspect of the lateral femoral condyle and runs anteriorly to insert in between and in front of the tibial spines to resist anterior displacement of the tibia relative to

the femur.

- The posterior cruciate ligament (PCL) runs from the anteromedial aspect of the medial femoral condyle to the posterior tibial sulcus to resist posterior displacement of the tibia relative to the femur.
- The extensor mechanism crosses the knee joint anteriorly and inserts onto the tibial tubercle.
 - It is composed of the four muscle bellies of the quadriceps, the quadriceps tendon, the patella, the patellar ligament, and the medial and lateral patellofemoral retinaculum.
 - It is critical to normal ambulatory function.
- The superficial femoral artery courses down the femur on the medial side underneath the sartorius muscle and then passes through the adductor hiatus to run posterior to the knee in the popliteal fossa where it becomes the popliteal artery.
 - It provides the sole blood supply to the distal extremity and, if compromised, risks viability of the leg and foot.
- The main blood supply to the knee is provided from superior and inferior lateral genicular arteries, the superior and inferior medial genicular arteries, the anterior recurrent tibial artery, and the descending genicular artery.
 - These form an anastomotic ring around the patella.
- The femoral nerve crosses the knee at the medial aspect and becomes the saphenous nerve supplying sensation to the medial leg and foot.
 - It gives off the infrapatellar branch as it crosses the knee, supplying sensation to the anteroinferior skin of the knee.
 - This nerve is sacrificed frequently during anterior midline exposures.
- The sciatic nerve bifurcates just above the popliteal fossa into the tibial and common peroneal nerves.
 - The tibial nerve joins the popliteal artery and runs directly posterior to the knee into the leg.
 - The common peroneal nerve crosses laterally and runs superficially around the neck of the proximal fibula before bifurcating in the deep and superficial peroneal nerves.
- The blood supply to the skin of the knee typically arises from medial to lateral.
 - This characteristic deserves careful attention when choosing which incision to use on a knee with multiple scars.
 - Typically the most lateral incision is chosen so that the potential area of skin

at risk for necrosis is minimized.

PATHOGENESIS

- Conditions that warrant bony debridement around the knee include open fractures, chronic osteomyelitis, and periprosthetic joint infections (PJI) after TKA.
- Bony debridement is frequently required to prevent or eliminate bacteria capable of forming biofilms.
- Bacteria can exist in either a planktonic or biofilm state.
 - In contrast to planktonic microorganisms that are free-floating and rapidly dividing, a biofilm is characterized by sessile microorganisms that are embedded in a matrix capable of withstanding both the host's immune system and antibiotics.
- Once bacteria colonize and adhere to the necrotic bone or implants, they can rapidly form a biofilm.
 - Surgical debridement and removal of any implants are the most efficacious method to eradicate infection.

Open Fractures

- Open fractures involving the patella are the most common with an incidence of 6 per million per year in the general population, followed by the distal femur (5.6 per million per year) and proximal tibia (3.8 per million per year).
 - Road traffic accidents are the primary mechanism.
- The Gustilo classification system for open fractures was first published in 1976, modified in 1984, and arguably remains the most commonly used system in orthopedic surgery.^{1,2}
 - This system organizes open fractures in order of worsening prognosis according to the degree of soft tissue injury, need for soft tissue coverage and vascular insult.
 - Type I: usually low energy, clean, and involve an open wound less than 1 cm in size
 - Type II: intermediate-energy, moderately contaminated wounds greater than 1 cm (but less than 10 cm)
 - Type III: farm injuries or high-energy fractures with periosteal stripping and extensively contaminated open wounds greater than 10 cm:
 - IIIA wounds can be managed with local wound coverage and skin graft

only.

- IIIB requires rotational or free flap coverage.
- IIIC is associated with arterial damage.
- The risk of infection has been shown to directly correlate with the fracture grade.
- The true extent of underlying soft tissue damage can be appreciated only after surgical exploration and debridement in the operating room, rather than in the emergency department.
- All open fractures are considered contaminated with bacteria, and antibiotics must be administered as early as possible to prevent infection.
- Patzakis et al. found an infection rate of 4.7% compared to 7.4% when antibiotics were given within 3 hours of injury.³
- The choice of the antibiotic depends on the degree of injury and level of contamination.
 - Intravenous first-generation cephalosporins, such as cefazolin, are considered first line.
 - For Gustilo type III open fractures, extending the coverage to include gram-negative bacteria by adding an aminoglycoside is commonplace.

Osteomyelitis

- Osteomyelitis can arise from hematogenous seeding, contiguous spread from adjacent tissues or joints, or direct inoculation from surgery or trauma.
- Hematogenous spread of bacteria typically afflicts the metaphysis in skeletally immature patients but can also seed implants especially in the case of TKA.
- Contiguous spread and direct inoculation are seen after direct contamination from open fractures or surgical procedures.
- The duration of symptoms designates osteomyelitis as either acute or chronic and carries important implications with regard to biofilm formation and the need for surgical debridement.
- The Cierny-Mader classification system is commonly used to categorize osteomyelitis based on the extent of bony involvement and status of the host and carries prognostic value in addition to guiding therapy.
 - Type I involves only the medullary canal.
 - Type II involves a portion of the cortex.
 - Type III is an infection that permeates the cortex into the canal, but the bone

is axially stable.

- Type IV is similarly permeative but diffuse and places the bone at risk for fracture.
- The status of the host is divided into classes A, B, and C.
 - The A host is physiologically healthy.
 - The B host has compromised physiology from systemic effects of the infection or medical comorbidities.
 - The C host is classified as one in which the morbidity of the treatment is greater than the disease.
- Sequestrum is a key pathologic feature of osteomyelitis and represents the formation of necrotic bone.
- Bacteria persist in devascularized bone and evade host defenses and antimicrobial agents.
- The response of the host is to generally wall of the “bony abscess” by forming sclerotic bone around the sequestrum.
 - This is known as the involucrum.

Infection After Total Knee Arthroplasty

- Periprosthetic joint infection after TKA is a devastating condition that occurs in 0.5% to 1.9% of primary TKAs and in 8% to 10% of revision TKAs.⁴⁻⁶
- The implants provide an excellent surface for bacterial adherence, biofilm formation, and facilitate the spread of the microorganisms into the surrounding bone and soft tissues.
- Infections can occur in the perioperative period or years later after a previously well functioning TKA.
- The longer the duration of symptoms, the greater chance of biofilm formation on the implants and surrounding bone.
 - Symptom duration is commonly separated into acute (3 weeks after surgery or symptom onset) and chronic (greater than 3 weeks after surgery or symptom onset).
 - Aggressive surgical debridement and implant removal are key interventions to treat infections with suspected biofilm formation.
- Conditions that warrant soft tissue debridement around the knee include open fractures, septic arthritis, and PJI after TKA.
- Soft tissue debridement is frequently required to prevent or eliminate bacteria capable of forming biofilms.

PATIENT HISTORY AND PHYSICAL FINDINGS

Open Fractures

- Any patient presenting with an open fracture may have associated injuries to the head, chest, abdomen, pelvis, spine, and extremities.
- A standard evaluation according to the Advanced Trauma Life Support guidelines should be performed to evaluate for all potentially life-threatening injuries.
- The injury mechanism and details are helpful as high- vs low-energy injuries predict the extent of bony and soft tissue injury.
 - Low-energy trauma with an open fracture may be associated with a small inconspicuous poke hole created from inside-out injury.
 - High-energy trauma usually creates a much larger soft tissue defect or frank degloving of the skin and subcutaneous tissues.
- A detailed neurovascular exam of the lower limb involved should be done with focus on evaluating the function of the peroneal and tibial nerves, as well as the dorsalis pedis and posterior tibial pulses.
- Any suspicion of vascular injury may direct appropriate testing and consultation with a vascular surgeon.
- The soft tissues must be thoroughly inspected.
 - Any fracture with a nearby skin laceration or defect should be considered open until proven otherwise by surgical evaluation or saline challenge, utilized in evaluation of traumatic arthrotomy and to determine the presence of possible external communication with the knee joint.

Osteomyelitis

- Symptoms and signs of infection should be elicited from the patient including fever, chills, pain, and swelling.
- Prior injuries and surgeries including the presence of hardware are important to identify.
- The general medical status of the patient including factors that can contribute to an immunocompromised state should be investigated.
- The involved limb should be inspected for erythema, swelling, tenderness, and any opening in the skin that might suggest a draining sinus tract (**FIG 1**), which is indicative of chronic osteomyelitis.
- The neurovascular status of the limb should be evaluated as well as the quality

of the soft tissues.

- The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are markers of inflammation that are typically elevated and can be useful for monitoring response to therapy.
- The white blood cell count may be normal in cases of chronic infection.

FIG 1 • Draining sinuses as a result of chronic periprosthetic knee infection.

Infection After TKA

- PJI may present acutely after surgery with persistent pain and drainage from the incision with overlying cellulitis or in a delayed fashion with pain only (**FIG 2**).
- Any pain, stiffness, or instability should warrant consideration of an infection until proven otherwise.
- Special attention should focus on the scars about the knee and neurovascular status of the limb.
- Multiple scars or poor-quality tissues may necessitate the early involvement of a plastic surgeon for soft tissue coverage at the time of the planned surgery.
- An ESR greater than 30 and CRP greater than 10 mg/L are recommended as the thresholds indicative of chronic infections.
- If there is any suspicion of PJI, the knee should be aspirated and the fluid sent for cell count, gram stain, and culture.
 - Importantly, the entry point of the needle for aspiration should not involve any skin with overlying cellulitis.
 - An aspiration that yields greater than 1700 cells/ μ L with a neutrophil

percentage greater than 65% is highly suggestive of PJI.

FIG 2 • A. Wound dehiscence postoperative day 14 in a 55-year-old woman with diabetes mellitus s/p total knee arthroplasty for osteoarthritis. **B.** Skin necrosis in a 25-year-old woman after patellofemoral arthroplasty for post-traumatic arthrosis.

IMAGING

Open Fractures

- Orthogonal radiographs of affected area including the joint above and below are important for characterizing the fracture pattern and detecting concomitant injuries, which are frequent in high-energy trauma.
- For open extra-articular fractures involving the proximal tibia or distal femur, plain radiographs are typically all that is required for surgical planning.
- This is true also for isolated open fractures of the patella.
- Fractures involving the tibia plateau or distal femoral condyles may be complex and require computed tomography (CT) to better visual the fracture patterns and to facilitate optimal surgical planning.
- CT angiography may be considered if there is suspicion for vascular injury.
- Magnetic resonance imaging (MRI) is not typically warranted in the acute period but may be obtained eventually if ligamentous or meniscal damage is suspected.

Osteomyelitis

- Radiographs of the involved limb should be obtained in orthogonal planes.
 - In the acute stages of osteomyelitis, the films may be unremarkable.
 - A lytic lesion may be appreciated when enough of the bone has eroded.
 - In chronic situations, the sequestrum may form and is characterized by a sclerotic focus of infected and necrotic bone that may be surrounded by a thickening of the surrounding cortex known as the involucrum with periosteal reaction.
- Computed tomography is more sensitive and better shows the bony destruction from the lesion compared to plain films.
- Magnetic resonance imaging is the most sensitive modality especially in the early stages of osteomyelitis and will show the extent of intramedullary and soft tissue involvement.
- Nuclear bone scans are a sensitive modality but nonspecific.

Infection After TKA

- Standard radiographs should be obtained and may show osteolysis with component subsidence or loosening.
- CT scans, MRI, and nuclear bone scans of little use in preoperative planning and are not typically needed.

SURGICAL MANAGEMENT

Open Fractures

- Historically, the practice in orthopedic surgery has been to perform operative debridement within 6 hours after injury to minimize the risk of infection, but there may be no advantage to performing the debridement within this time frame compared to within 24 hours after injury.
 - A thorough debridement by an experienced team during daylight hours with the appropriate ancillary staff appears to be the critical factor in preventing infection.
- All devitalized and contaminated soft and bony tissue must be identified and removed in a systematic fashion.
- Bony damage can be highly variable and demands thorough intraoperative inspection.
 - The decision of whether to retain or discard bony fragments depends on the remaining soft tissue attachments and involvement of the diaphysis, metaphysis, and articular margins.

- Diaphyseal fragments that are stripped of their soft tissue attachments are effectively devascularized and must be removed, to prevent a nidus for infection.
- Metaphyseal fragments, in contrast, have a greater amount of cancellous bone, which has a greater capacity to revascularize and reintegrate.
 - Thus fragments that have minimal contamination may be retained.
- Cancellous fragments from the articular margins are also retained in order to anatomically reconstruct the articular surface.
- Repeat debridement may be necessary 24 or 48 hours later, as the zone of injury may be more extensive than initially appreciated.
- Thorough irrigation of the wound after debridement should be performed using the rationale that “the solution to pollution is dilution.”
- Once the wound has been debrided back to healthy and viable soft tissue and bone, attention must be turned to achieving skeletal stabilization.
 - Stabilizing the bone is critical for creating an environment conducive not only for bone healing but soft tissue healing as well.
 - Stabilization also facilitates early mobilization of adjacent joints, preventing stiffness and further disability of the injured limb.
 - Options for stabilization will depend on the need for repeat debridement and soft tissue coverage.
 - The wound should be definitively closed within 48 to 72 hours after fracture fixation.
 - If injury is a type IIIB open fracture, then external fixation may be preferred to allow unimpeded access to the wound for soft tissue coverage followed by definitive internal fixation after the soft tissue envelope has been re-established and healed.
- High-energy injuries may result in substantial bony or soft tissue loss from the initial injury with subsequent debridement procedures creating extensive dead space.
 - Temporary antibiotic-impregnated polymethylmethacrylate (PMMA) cement beads can be placed into bony defects and used to deliver high doses of antibiotics locally.
 - Alternatively, negative pressure wound therapy may be used for similarly large soft tissue defects.

Osteomyelitis

- Once the diagnosis of osteomyelitis has been made, it requires proper staging and a multidisciplinary approach with involvement of infectious disease specialists, orthopedic surgeons, and plastic surgeons especially if the need for soft tissue coverage is anticipated.
- Though acute hematogenous osteomyelitis without associated implants may be amenable to intravenous antimicrobial therapy alone, infections that are chronic, are associated with implants, or have an identified sequestrum will require aggressive surgical debridement if the goal is to eradicate the infection.
- All dead and nonviable bone should be removed until punctate bleeding bone is encountered.
- In the case of intramedullary infections, intramedullary reaming of the canal is an effective way to debride contaminated bone while preserving cortical stability.
- The placement of antibiotic impregnated PMMA cement into the bony and soft tissue defect to deliver high concentrations of antibiotics to the local tissue has become standard in the surgical treatment of osteomyelitis.
 - Current techniques include using an antibiotic coated intramedullary nail for situations involving the medullary canal of the tibia or femur.
 - For well-localized areas and bony defects created after the debridement, antibiotic-impregnated cement may be packed into the defect or rolled into beads and attached to suture for easy extraction and to provide a high surface area to volume ratio in order to maximize drug elution.
 - As the cement is not biodegradable and may continue to elute low levels of antibiotics for up to 5 years following implantation, a repeat procedure is typically required for removal of the cement and bone grafting of the defect to restore skeletal stability and eliminate dead space.
 - Bioabsorbable composites such as calcium sulfate have been examined as an alternative for dead space fillers and antibiotic delivery vehicles.
 - These materials have the benefits of being resorbed and possibly being replaced by bone, thus potentially eliminating the need for a second procedure.
 - McNally et al. reported an excellent eradication rate of chronic osteomyelitis treated with one stage debridement and placement of an antibiotic-impregnated bioabsorbable composite.

Infection After TKA

- The timing and duration of the infection have important implications with regard to treatment.
- An early infection is defined as occurring within 3 weeks after undergoing the procedure or within 3 weeks after becoming symptomatic in cases of late hematogenous infection.
- Late infections are considered all cases that present more than 3 weeks after the above.
- The designation of 3 weeks is based on the theoretical time period that it takes for bacteria to form biofilms.
- To prevent the morbidity of explanting components, early infections are typically treated with aggressive debridement and irrigation, exchanging the polyethylene liner, and retaining the femoral and tibial components.
- Late infections are most commonly treated by a two-stage exchange arthroplasty in the United States.
 - The microorganisms by this time have likely adhered to the implants and formed biofilms, undermining the efficacy of systemic antibiotic therapy.
 - The first stage is composed of removal of all implants, cement, and infected tissue.
 - Although minimizing bone loss is a priority, the surrounding bone can contain biofilm and must be debrided back to healthy punctate bleeding bone.
 - Irrigation is then performed, and an antibiotic-impregnated cement spacer is placed to provide stability, fill dead space, and deliver high concentrations of local antibiotics.
 - The spacer can be dynamic or static.
 - Dynamic spacers involve the use of articulating components that allow for knee range of motion.
 - Static spacers typically involve antibiotic cement-coated humeral nails that bridge the knee after being placed in the distal femoral and proximal tibial canals.
 - Intravenous antibiotics that target the identified organism are then given for 4 to 6 weeks. Once the patient has finished the course of antibiotics and has been off therapy for 2 weeks, repeat inflammatory markers are drawn. If the ESR and CRP are normal, and the clinical exam is negative for any suspicion of persisting infection, reimplantation is then considered.
 - This entails removal of the antibiotic spacer, a thorough repeat irrigation and debridement and obtaining several intraoperative tissue specimens for

cultures.

- It is important to remove the pseudomembrane that forms between the cement and the bone in the intramedullary canal with instruments such as a ringed curette.
